LIST OF CONTRIBUTORS TO VOLUME CXVIII.

Those whose names are marked with an asterisk have contributed editorial articles.

Allport, Frank, M. D., Chicago.
Anderson, John F., M. D., New Brunswick, N. J.
Arkin, Morris L., M. D., Chicago, Ill.

*Baar, Gustav, M. D., Vienna, Austria.
Baldwin, Jane, M. D., New York.
*Bancroft, Frederick, M. D., New York.
Barker, Lewellys F., M. D., Baltimore, Md.
Bassler, Anthony, M. D., New York.
Benjamin, Harry, M. D., New York.
Bennett, A. E., M. D., Philadelphia, Pa.
Bernstein, Henry A., M. D., New York.
*Boas, Ernst F., M. D., New York.
Boston, L. Napoleon, M. D., Philadelphia, Pa.
Bram, Israel, M. D., Philadelphia, Pa.
Bransfield, J. William, M. D., Philadelphia, Pa.
*Brink, Louise, A. B., New York.
Brooke, Charles R., M. D., New York.
Brown, Aaron, M. D., New York.
*Brown, Mabel W., B. A., New York.
Brumberg, Joseph, M. D., Buffalo, N. Y.
Brunet, Walter M., M. D., Brooklyn, N. Y.
Bullowa, Jesse G., M. D., New York.
Burch, John H., M. D., Syracuse, N. Y.
Burrows, Elliott C., M. D., New York.
Burrows, Waters F., M. D., New York.
Butts, Donald C. A., Philadelphia, Pa.

Cahn, Lester R., D. D. S., New York.
Cannon, A. Benson, M. D., New York.
Carroll, Robert S., M. D., Asheville, N. C.
Case, James T., M. D., Battle Creek, Mich.
Cheplin, Harry A., Ph. D., Syracuse, N. Y.
Cherry, Thomas H., M. D., F. A. C. S., New York.
Chesney, W. D., M. D., Chicago, Ill.
Clark, William Earl, M. D., Washington, D. C.
*Clouting, Charles A., M. D., London, England.
Cohen, Harry, M. D., New York.
Cornwall, Edward E., M. D., F. A. C. P., Brooklyn, N. Y.
Cotton, Waite A., D. D. S., New York.
Crampton, C. Ward, M. D., New York.
Crance, Albert M., M. D., Geneva, N. Y.
Crawford, B. L., M. D., Philadelphia, Pa.
Crispell, Raymond S., M. D., New York.
Cross, Ernest S., M. D., Baltimore, Md.
Culver, George D., M. D., San Francisco, Cal.

Physiotherapy*

By NORMAN E. TITUS, M.D.,

New York.

Most papers dealing with physiotherapy that are presented to the general surgeons and medical men, are so restricted to a presupposed knowledge of physiotherapy, that it will be the effort of the writer to present physiotherapy for your consideration in the light of physics and physiology. I shall endeavor to show wherein physiotherapy is really a help to established surgical and medical procedures. There are many men who do this work who refuse to acknowledge that physiotherapy is mainly an aid in treatment, and endeavor to show where they can compete with established practices which are certainly more accepted by the medical profession as a whole.

Of course the older workers in physiotherapy have endeavored so much to treat every condition by these measures, that they frequently neglect due consideration of established surgical and medical practices. We younger men in this field, who are more trained in modern surgery and medicine, realize that our first duty is to use accepted operating room, laboratory, and ward treatments, and then, if possible, help out these procedures with physical measures.

The basis on which physiotherapy is applied is with the consideration that disease is an abnormal condition of the body which is acute in its course, if the reaction of the body to this disease is adequate. If, however, the reaction is inadequate, the disease continues, eventually becoming chronic. The use of physiotherapy in the treatment of disease is along the lines of an effort to convert this inadequate reaction into an adequate reaction. So with an understanding of the pathology encountered, the application of physical measures is indicated, if, through the physiological response, the inadequate reaction can be converted into an adequate reaction. It is often astonishing to patients who desire a prognosis of their condition to tell them that such cannot easily be given because it all depends upon how they themselves respond to the treatment.

Physiotherapy is a word coined by the army which includes treatment by all physical measures. The special divisions of physiotherapy are: electrotherapy, phototherapy, thermotherapy, hydrotherapy, actinotherapy, röntgenotherapy, massage, and exercise.

ELECTROTHERAPY.

Electrotherapy is the use of electricity in one of its many forms, and I shall present a brief description of these forms with their methods of inducing results.

1. *Galvanic electricity.*—This, the earliest form known, is a current flowing in one direction with a definite positive and negative pole. The action of this current is purely chemical, and it is used where ionization is required for the induction of chemicals into tissue. The positive pole has analgesic, hemostatic, and antiseptic actions, and repels bases, metals, and alkaloids. The negative pole is the opposite of the positive in the characteristics mentioned and repels acid and acid radicals. The negative pole has also the ability to soften scar tissue, and is frequently used to loosen adherent scars. Galvanism is also used in removing hair but this is a very delicate procedure. The negative galvanic current has been used extensively by some men to destroy urethral strictures.

2. *Faradic current.*—The faradic current is a pure, induced current (having no positive nor negative pole), and its greatest use is to produce exercise of muscles through the stimulation of the motor end plates in the muscles.

Both faradic and galvanic currents are applied with machines which cause variations in their strength, and these currents of varying strength, such as the sinusoidal current, have special uses.

3. *High frequency currents.*—These currents also have no definite positive or negative pole because they are of an alternating character and of such great frequency in alternation that the entire effect of these currents is due to their ability to generate heat when passing through a resistance, such as the body. There are two high frequency currents which are in general use—the d'Arsonval current applied with two electrodes, and the Oudin current applied with a single electrode. The d'Arsonval cur-

552308

rent is mainly used in two ways—for autocondensation and diathermy. Autocondensation is applied by the patient holding one pole in his hands placed on a cushion, the other pole being connected with metal plates on the opposite side of a cushion upon which the patient is seated or reclining. The cushion is a special nonconductor, and when the current is applied, the effort of the current to penetrate this nonconductor condenses the current in the patient and generates heat. This heat gives an actual rise in body temperature, whipping up all the processes of the body, and it has been found that blood pressure may be most satisfactorily reduced with this treatment. Investigations have shown that there is an increase in the expired carbon dioxide and in the specific gravity of the urine passed after a treatment. As an example of what autocondensation will do in the treatment of high blood pressure, I have looked over the records of about twenty-five cases and found that my maximum reduction has been fifty-two mm. and of course my minimum has been zero, and disregarding these negative reactions, my average drop in all cases has been fourteen mm. in each treatment. It is necessary to ascertain the correct dosage for each patient before results show during the course of treatments, and I have found that in forty-eight hours a patient's blood pressure will not rise more than thirty-five per cent. to forty per cent. of the amount which had been reduced.

The second way of using d'Arsonval current, called diathermy, is by the application of this bipolar current with two electrodes placed on opposite sides of the part in which one wishes to generate heat, and the current passsed directly through this part. It has been proved many times that the current is first generated in a spot equally distant between two electrodes of the same size, and then in the tissue the heat spreads from the centre out towards the electrodes. If the electrodes are of different sizes, the centre of heat generation varies in proportion to the square of the electrodes. This makes it possible to place a large electrode on one part of the body, and by use of a very small electrode such as a needle, apply diathermy in what the English call a surgical way for the destruction of tissue beneath the needle point. I have seen cases where the entire jaw and teeth have been destroyed by this means. In the use of what the English call medical diathermy, the electrodes are generally kept about the same size and this current is used with good results in joints and through the chest in bronchitis and even in pneumonia to increase the circulation by the generation of heat. In the past two years, diathermy has been used in cases of postapoplectic paralysis with an electrode on the forehead and one on the occiput to whip up the circulation within the brain itself and hasten the absorption of the clot. This heating of the brain has been proved by experiments on the heads of decapitated criminals where the brain has been actually cooked within the skull.

The Oudin ccurrent applied with one pole is used mainly in the destruction of surface growths and is successful in the treatment of epitheliomata above the mouth, and of warts and moles.

The fourth electrical modality used is the static current. This is extremely useful because it is of high voltage and low amperage, and has a definite positive and negative pole of which the positive is the most useful and analgesic, whereas the negative is very irritating. Perhaps a description of the difference between a static current and an ordinary high voltage current, such as that used in the x ray, will emphasize the fact that static electricity is purely mechanical in its effect. High voltage and low amperage mean great force with small volume, such as the shooting of a small dried pea in a ten inch mortar; the force of the explosion being the voltage and the pea being the amperage. If the ten inch shell is put in the mortar, the amperage is increased, and hence the effect of the current with the same force is much greater. So you see that static electricity is force under great pressure but of small volume, and people are amazed that they can stand five hundred thousand volts of this current without any detrimental effects.

There are three main ways of applying the static current, the exact description of which I shall not go into, except to call them the static wave current; where the patient is connected with only the positive pole and the current goes into but not through the patient, making the patient the condenser; the static sparks which are applied by grounding the current in the patient who is connected in the same way to the machine; and the static brush discharge is also used which has a pronounced sedative action and is useful in painful conditions where one wishes to use static electricity for its mechanical effect. The difference in technic in giving this treatment is that the patient is connected with the negative pole of the machine, the positive pole of which is grounded, and then from another lead from the earth, the positive current is conducted to the patient through a special applicator which causes it to go through the air as a brushlike effluve. This brush discharge in going through the air generates ozone and incidentally has been found successful in the treatment of styes.

I hope that this brief consideration of the uses of electricity will be sufficient to show you that with electricity we have, first a chemical means, one inducing exercise, one generating heat within the tissues, and a fourth which has a purely mechanical current far surpassing any effects which can be obtained by massage. For electricity makes the part work instead of working the part.

PHOTOTHERAPY.

As the name implies, photography is treatment by light. To understand the way in which light works, it is necessary to remember the old law, you all learned in physics, of the conservation of energy, and to realize that light energy when stopped becomes heat. It is also necessary to realize that light cannot be appreciated by the eye until it is stopped. Therefore if light penetrates through a tissue and we can see light on the other side of this tissue, we know it has penetrated through to the depth we see it. Consequently the light rays being stopped at this depth, generate heat there. Experiments have shown that it is very easy to expose films placed within the abdominal cavity and thorax by a shining light on the outer side of the abdomen or chest. So we know that in applying light to a muscle the light penetrates into the substance of the muscle and generates heat within the muscle itself. This is why counterirritation with light so far surpasses counterirritation by any other means, such as mustard paste, flaxseed poultices, or actual cautery. In treating with light there is also the effect of radiant heat. This is best exemplified in the warmth given off by these popular electric heaters with copper reflectors, and also directly by the sun. If the heat given off was the same as that given by a nonglowing source, the heat rays could be deflected by an electric fan or strong draught of air. We all know that if the sun is shining directly on snow it will melt, whereas two inches away in the shade the snow will not melt. The phenomenon is due to the effects of radiant heat which when used on patients does all that poultices, and other remedies do. Phototherapy is only used for the heat effect, and generally to increase the local circulation before the application of other measures, such as static electricity.

THERMOTHERAPY.

This is the use of dry heat in small electric bakers or large bakers in which the entire body is inserted. The action of dry heat and also vapor baths (which are moist heat) is to induce perspiration by surrounding the body with air of an increased temperature. It is my belief that electric light baths, due to the generation of heat within the tissues as well as the application of radiant heat upon the surface, are much more efficient than hot air or vapor baths.

ACTINOTHERAPY.

Actinotherapy is treatment with ultraviolet light. This light is purely germicidal in its effect, but lately it has been found that there is a distinct tonic effect in baths given with this light. Ultraviolet light is that part of sunlight which causes tanning of the skin, and it is very essential to realize that it will not pass through ordinary glass. The only available conductor of ultraviolet energy is pure quartz or the air. The ultraviolet light we have at our disposal is more efficient than the best sunlight obtainable on the earth's surface, because the wave lengths produced are shorter than the shortest rays of the sun. The unit of wave measurement is called an Angström unit. This is a wave length of one micron. The shortest waves from the sun are 2910 Angström units, whereas we can get from our quartz lamps wave lengths of 1850 Angström units, and it is much easier to blister a patient with ultraviolet light than with the actual sunlight. If, however, a patient is blistered there is no actual destruction of the deeper epithelium, and skin much smoother will grow where the blister has been induced. Realizing this advantage of ultraviolet light, wherever we have superficial infections of the skin or conditions of subacute infections of wounds, ultraviolet light is a distinct aid in the treatment of these infections.

There are two forms of quartz burners used for the generation of ultraviolet light—the aircooled which is a Cooper Hewitt mercury lamp, the tube of which is fused quartz; and a watercooled lamp in which the tube is surrounded by circulating cold water so that the heat from the boiling mercury is taken away and the lamp can be used closer to the skin or with quartz applicators attached to the front of it, applied to cavities or sinuses. The aircooled lamp has practically no further penetration than a millimetre but the watercooled lamp penetrates about one tenth of an inch, and if the applicator is pressed upon the skin, can be made to penetrate about one quarter inch. I have seen truly remarkable results in cutaneous infections (especially in furuncles before the formation of pus) achieved by the use of ultraviolet light. I might also mention that Major C. M. Sampson of the Public Health Service last year attained honorable mention in the Leonard Research Prize Contest of the American Röntgen Ray Society for his work in using ultraviolet light to increase gradually the skin resistance to x ray. He was able to give doses of x ray without disastrous results which, I am sure, most x ray men consider unbelievable. Major Sampson has also been universally successful in the treatment of x ray burns with ultraviolet light, and this field promises a future which will undoubtedly aid x ray therapy in years to come.

HYDROTHERAPY.

Hydrotherapy is superficial in its direct action, but indirectly we have a means to produce a sedative or an intensely stimulating secondary reaction in the body or on parts to which it is applied. The use of the whirlpool baths where the water is kept constantly agitated by means of air, was found in the army to be the greatest help in the treatment of injured peripheral nerves and stumps after amputation.

X RAY.

The subject of x ray therapy is making so many advances from day to day and so many just and unjust claims are being made for it, that I feel that merely a brief mention of its indications are all I should discuss in this paper which is on physiotherapy. X ray therapy is a part of physiotherapy but demands such extensive investigation and exclusive attention, due to the broadness of its field, that a detailed discussion should always be taken up in a paper devoted to that subject by itself. Undoubtedly the x ray is a marvelous aid in therapeutics. It has been supposed that it would supplant many surgical procedures, but it is mainly pushed by the army of enthusiasts who believe they have found something to supplant good old surgery. Undoubtedly the action of the x ray on tuberculous glands is the procedure of choice because of the difference in cosmetic results. This is one of the oldest things that has been treated with x ray, and when first brought out, was laughed at by many surgeons. I remember my father reported fifty cases successfully treated in 1905, and was credited with being the author of great amusement rather than progress. He noted then that the tonsils in these cases were all affected by the x ray, and lately a wave of enthusiasm among some x ray men has pushed the discussion of the effect of the x ray on tonsils to almost a bitter fight. I, personally, believe that the treatment of tonsils with x ray is only indicated where operation is contraindicated. As I have said, this is merely my personal opinion. The preoperative and postoperative treatment of malignant growths is a method to be most heartily endorsed, and I am sure will be more adopted as time goes on. With these brief words to you about the great subject of x ray therapy, I wish to close with an apology to the serious workers in this field for not giving it more complete discussion.

MASSAGE.

Massage is probably one of the oldest forms of physiotherapy, and it has its distinct field in its application to patients who are confined in bed or in a hospital. It also is of use in paralyses and muscular atrophies. Of course there are many ambulatory patients with affected extremities where long continued massage is of distinct help. I do feel, however, that in acute conditions, electricity will produce better and quicker results than massage, for as I said above, electricity makes the part work.

EXERCISE.

Exercise in the treatment of some conditions has made a distinct field for itself. It includes the use of parts of the body which have been limited in their motion, generally through result of some infection or as happened in the war through injuries acquired in the wounded. The different exercises given to men with ankylosed joints and contracted scars helped them in time to acquire remarkable increase in function. It has also been found in the treatment of flat foot that walking on a path of a double inclined plane helped to strengthen the feet and acquire better support. This field belongs more to physiotherapy as applied to orthopedics, and, as in most orthopedic procedures, the results obtained are generally good but take time to achieve. There are exercises used in the reeducation of muscles in paralytics and tabetics and which are of some help, of course with other treatments, and under the head of exercise it was found that boxing and dancing had their place in the big hospitals of the army.

CONCLUSION.

I hope that I have not made the subject of physiotherapy seem to be the least bit mysterious, and that I have been in some way able to show that we who practice physiotherapy want to help both the surgeon and the physician in any way that we can. Physiotherapy is really an aid in established practice, and though there are a few things we can do quicker than with the ordinary surgical or medical procedures, we younger men in this work are most sincere in our desire to cooperate rather than to supersede in the treatment of patients who come to us.

100 EAST FIFTY-FIFTH STREET.

Physical Therapy

By JOHN H. BURCH, M.D.
Syracuse, N. Y.

Notwithstanding the fact that we are emerging from a cycle of therapeutic nihilism, it requires some temerity to present a paper on physical therapeutics.

The suggestive effect of the various electric machines emitting weird lights and startling sparks, was readily made use of by shrewd charlatans to extort money from their credulous victims. The semiquacks within the medical profession also exploited the various methods of physical therapy to the extent that the honest physician became unduly prejudiced against all forms of electrical and mechanical methods of treatment.

The profession is beginning to inquire just what type of cases may be benefited by the various electrical, mechanical and phototherapeutic methods of treatment. No little surprise and chagrin are manifested when a trusted patient reports that he has been cured by an osteopath, a chiropractor or an advertising quack who makes use of physical methods of treatment. Many reputable physicians refer their patients to osteopaths, the barber who installs electrical equipment, or the hospital technician, rather than perfect themselves in these methods of treatment or to confer with their confrères who have diligently sought to sift the few grains of truth from the great bulk of chaff regarding the effects of these natural methods made use of in medicine and surgery.

PHOTOTHERAPY

Light exercises a stimulating influence on the functions of tissue elements and organs. The energy infused into the body by light is transformed into a stimulus quickening all vital processes. Light influences directly the protoplasm of the irradiated cell, or, by its indirect action through the sense organs and nerves stimulates certain functions of the various organs.

Light falling upon and irradiating the body will either be absorbed producing chemical effects, or, it will be converted into heat increasing absorption phenomenon, or give rise to electrical phenomena, setting up electric currents within the tissues. These processes are frequently simultaneous and it is difficult to separate the effects of the different rays of the spectrum.

DeParville's experiments seem to prove that the red end of the spectrum is nerve irritating and that the reverse, blue and violet are nerve sedative. The bactericidal effect of light is well established and familiar to all. It has been definitely proved that the germicidal action of light is due almost entirely to the blue violet and ultraviolet radiations. The effect of light upon the skin is well known. It produces a specific dermatitis and characteristic tanning.

It has been demonstrated by means of especially prepared photographic plates that red, green, blue, and perhaps, blue violet radiations have the power to penetrate living tissue. The greater portion of the ultraviolet radiations are absorbed by the skin. In this process of absorption, however, powerful chemical changes are induced. Of great importance in this connection is the effect of these absorbed radiations upon the blood. Hemoglobin is the constituent of the blood that uniformly absorbs light. Quincke demonstrated that hemoglobin gave of its oxygen more readily in light than in darkness; thus demonstrating that light increases the oxygenating power of the blood and consequently the processes of oxidation of the body. It will be seen, therefore, that there is a rational basis for the therapeutic application of light.

In utilizing light as a therapeutic agent we may employ direct sunlight, the arc light, or better still, the mercury vapor quartz light and the incandescent lamp. Sunlight in our climate is very uncertain and can be but little utilized. In the sunlight that reaches us most of the ultraviolet radiations have been absorbed by the dust. The therapeutic effect of sunlight is therefore dependent upon the blue violet and less refrangible rays of the spectrum. The arc light or better still the mercury vapor light is far more satisfactory.

The work of Finsen in the treatment of lupus by means of reflected sunlight and later by a powerful arc light was the greatest contribution to scientific phototherapy. Finsen demonstrated the potency of light in the treatment of lupus and placed light therapy upon a rational basis.

Rollier's observations upon the treatment of tuberculosis by means of heliotherapy are of the greatest importance. Rollier affirms that sunlight exercises a powerful action on the nourishment of living structure and that as certain of the spectral radiations penetrate into the depths of the organism, or, as the other more refrangible radiations are absorbed in their passage and converted into other forms of energy, that they bring about an increased metabolism of all tissues. The action is simultaneously bactericidal, oxidizing, pain relieving, granulating and tissue modifying.

The therapeutic effect of the incandescent lamp is largely due to radiant heat. Few violet and no ultraviolet radiations pass through the glass walls of the lamp. The favorable effect of this form of light in the treatment of infective processes of internal organs must be due to the stimulating action of these radiations upon metabolism and in increasing phagocytosis. I have found the high candlepower incandescent lamp of value in the treatment of acute painful conditions such as neuritis, acute bursitis, irritable spine, acute inflammatory joint affections and in hastening the absorption of serous exudates in joints and in pleural and peritoneal cavities.

I recall a case of persistent trifacial neuralgia that had resisted all methods of treatment that was readily cured by means of a 60 watt blue incandescent light bulb. I have found this treatment also of value in the management of superficial inflammations and suppuration. A case of suppurating tuberculous gland was quickly cured by means of a high power electric lamp.

Rollier found sunlight of value in the treatment of all forms of tuberculosis, but more especially in the management of tuberculous arthritis, peritonitis, and urinary tuberculosis. It has been found that the work done by Rollier with mountain sunlight may be accomplished more quickly by means of the mercury vapor quartz lamp.

The work of Alfred Hess and his coworkers has demonstrated the value of light in the treatment of rickets. In this work sunlight was first employed with gratifying results. As unfiltered sunlight is difficult to obtain in all locations, the mercury vapor and arc light were substituted with more uniform results.

Phototherapy has proved valuable in the treatment of certain skin affections. In the management of lupus and port wine marks the water cooled mercury vapor lamp is of great value.

I have successfully treated chronic dry eczema and acne vulgaris by means of a high power incandescent lamp. I have recently treated three cases of pruritis vulvæ by means of a mercury vapor quartz lamp. One of these patients was quickly relieved, another was somewhat benefited, while the third patient showed no perceptible improvement.

The mercury vapor lamp is being employed in the treatment of malnutrition and the simple anemias, the basis for its use being that the hemoglobin absorbs oxygen and imparts it more readily to the bodily structures under ultraviolet irradiation. I have six such cases now under observation, but it is too early to report results.

MECHANICAL VIBRATION

Kellogg says: The spine may be likened to a harp with a thousand strings. By the accurate manipulation of certain spinal areas, the function and metabolism of distant viscera in neural connection with the spinal segment over which the stimulation is applied may be modified at will.

If vibratory stimulation is applied over the posterior branch of a spinal nerve the stimulus is imparted to the sympathetic ganglia with which it is connected, which, in turn, conveys the stimulus or inhibition to the distant viscera it controls, thereby modifying its function.

While the medulla is the chief vasomotor centre, there are also subsidiary centres located at various levels of the spinal cord. The gray rami communicantes pass from the sympathetic ganglia to the spinal nerves and are distributed with them to the skin and bloodvessels.

By means of mechanical vibration, manipulation, or other physical agents, it is possible through this neural mechanism to modify the function of distant structures and viscera. It is well known that the irritation and hyperemia resulting from a gastric ulcer may cause pain, tenderness and muscular spasm in the lower dorsal region. By means of vibration we not only relax local spasm, but by so doing we relieve local stasis and pressure upon the posterior spinal nerve terminals. By relieving local muscular spasm, stasis and pressure, we also modify the circulation, innervation and metabolism of the organ supplied by the communicating branch of the spinal nerve.

Herein lies the danger of this system of therapy. While innervation, function and metabolism may be somewhat modified by means of spinal manipulation, we would not expect it to effect a cure of gastric or duodenal ulcer. It will, however, relieve gastrospasm and the pain resulting from peptic ulcer. It is upon this principle that such cults as osteopathy and chiropractic are based. These practitioners claim to discover subluxations and deviations of the spinal alignment that encroach upon adjacent structures thereby impinging upon the posterior spinal nerve terminals that cause disturbances in remote organs. Repeated x ray examinations have convinced me that such subluxations and malalignments are mostly myths. The apparent abnormality is almost always the result of muscular spasm. Subluxations of the various vertebræ are, however, possible and occur more frequently than has hitherto been recognized.

Various vasomotor centres are situated at different levels of the spinal cord, those controlling the head being between the 2nd and 6th cervical vertebræ. Deep pressure over this area will many times relieve cerebral congestion and hyperemia of the nasal and pharyngeal mucosa. The systolic blood pressure may be lowered by deep vibration on either side of the interspace between the 7th cervical and 1st dorsal vertebræ. I have seen, by means of the fluorescent screen, a sluggish ptosed hypotonic stomach contract vigorously when vibratory stimulation was applied on either side of spine between the 3rd and 5th dorsal vertebræ. Recently I studied such a case, that of a long stretched stomach with no apparent tone and deficient peristalsis. This stomach was located in the vertical position, the lower border of its greater curvature being below the crest of the ilium in the prone position. Vibratory stimulation was applied on either side of the 3rd, 4th and 5th dorsal vertebræ. The stomach was observed during this process by an assistant holding the fluorescent screen. Within a few seconds after the application of the vibration the stomach seemed to manifest tone. A deep peristaltic wave was seen. The stomach contracted and assumed an oblique position. The stomach was further observed for a few moments and its tone and peristalsis continued. Deep and longer continued pressure was then applied over the same area, with the idea of inducing inhibition. Under this vibration the stomach seemed to lose its tone. Peristalsis became more feeble and in a few seconds the stomach dropped back into its vertical position. This would seem to demonstrate the double effect that may be induced by vibration; a light stroke causing vasomotor stimulation while a longer stroke with deeper pressure induces inhibition.

Ocular muscular imbalance, cerebral or meningeal hyperemia, inflammatory processes involving the nasal and pharyngeal mucous membrane may induce contraction and rigidity of musculature of the suboccipital triangle. Deep vibration with sufficient pressure and length of stroke, applied on either side of the interspace between the spinous processes of the 2nd, 3rd and 4th cervical vertebræ, will many times relieve a hyperemia of the nasal and pharyngeal mucous membrane and cerebral hyperemia.

I remember a case of hiccough that occurred in my practice that resisted all methods of treatment. The situation at last became desperate. Finally, deep pressure was made along the anterior border of the scalenus anticus muscle to inhibit the phrenic nerve. This manipulation quickly arrested the hiccough. It returned, however, and the procedure had to be repeated. Each paroxysm became less alarming and it was finally controlled by this method.

The pulse beat may be slowed by vibration over the suboccipital triangle. It may be accelerated by vibration over the side of the 2nd, 3rd and 4th dorsal vertebræ. The vasomotor sensory centre is located between the 4th and 5th dorsal vertebræ. I once relieved a severe attack of angina by deep manipulation and pressure over this area. The pulmonary vasomotor control centre is said to be located between the 1st and 7th dorsal vertebræ. The liver and spleen receive their sensory and vasomotor innervation from the 8th, 9th and 10th dorsal nerves. The liver may be influenced by vibration between the 10th and 11th dorsal vertebræ, the ovaries between the 11th and 12th dorsal vertebræ. The kidneys between the 12th dorsal and 1st lumbar vertebræ. I have upon three occasions fluoroscopically observed a mass peristalsis of the colon take place after vibratory stimulation of both sides of the first, second and third lumbar vertebræ. This phenomenon, however, is not constant and it would require repeated observations to demonstrate that the occurrence as observed was the result of the vibratory stimulation.

From the foregoing it will be seen that vibratory stimulation or inhibition applied over the posterior branches of the spinal nerves will, through their ganglionic connection with structures and viscera, produce marked functional and metabolic reactions. My experience has taught me that it is in functional abnormalities that this method is of the greatest value.

The danger of this system of therapy lies in the ignorance of the cults who practise it in attempting not only to treat all manner of ailments by this method, but also, in basing a system of diagnosis upon apparent spinal abnormalities.

ELECTRICITY

While each of the various forms of electrical energy made use of in medicine produces its own characteristic physiological effect, the action upon general metabolism is similar. The static wave current applied over the hepatic area, the constant current with large electrodes placed over the abdomen and back, the sinusoidal, the faradic, and the high frequency currents cause an increase in the urinary solids, an increase in the elimination of urea and creatinin and an increase of sulphur and nitrogen.

The physiological action of static electricity is due, it is thought, to its penetrating vibratory effects, and is largely mechanical. It modifies arterial tension, lessens the heart's frequency, lengthens its diastole, and increases the pulse volume. It increases the depth of respiration and causes an increased elimination of carbonic acid. It relieves muscular irritability and induces a soporific effect. It induces diuresis and diaphoresis and increases the elimination of urea. The static breeze current is valuable in the treatment of insomnia, especially if accompanied by an irritable spine. The static wave current is valuable in the treatment of local stasis and sprains. Acute bursitis and some forms of neuritis are also benefited by this treatment. This current is also of value in the treatment of sciatica and sacroiliac strain.

The action of the direct or galvanic current is largely chemical and electrolytic. Ionization is the transmission of the constant current by the ions already existing in the tissues of the body. This ionic interchange within the deeper structures induces complex chemical changes that stimulate metabolism. In the passage of this current through the body resistance is encountered that converts electrical energy into heat, that likewise stimulates metabolism. The constant current induces distinct polar effects. An acid reaction is present at the positive pole, while an alkaline reaction characterizes the negative terminal. The positive pole is sedative while the negative is stimulating. The positive is styptic, arresting hemorrhage, while the negative softens cicatrices and dilates constricted orifices. The constant current stimulates and induces contraction of muscles. In the normal reaction the negative is more stimulating than the positive pole and causes a more vigorous contraction of a normal muscle when applied to its motor point. In certain pathological conditions the formula is reversed and the muscle responds more vigorously to the positive electrode. This is the well known phenomenon of the reaction of degeneration. The constant current also stimulates the vasomotor nerves.

Personally, I have employed the constant current in muscle testing and in the treatment of neuritis of the socalled idiopathic type where no apparent focal infection was found. In the treatment of peripheral paralysis the constant current is the most useful form of electrical energy. It should always be used when the paralyzed muscles fail to respond to the faradic current. The electrical treatment of peripheral paralysis should always be directed by a competent physician and only when a careful reaction test has been made.

Electrolysis is perhaps the most satisfactory treatment for the removal of moles, warts and nevi. Formerly I found the constant current of great value in the treatment of arthritis; especially the hypertrophic variety. Since the advent of diathermia I have largely abandoned this method as the direct high frequency current is more efficacious in the treatment of this condition.

The faradic current is utilized in muscle testing and in the treatment of peripheral paralysis. This current is also of value in the management of sensory disturbances such as anesthesia and acroparesthesia.

The sinusoidal current is peculiar from the fact that it is a sine wave that gradually increases from zero to its highest peak of intensity, from which it again recedes back to zero. It causes powerful and painless contraction of muscles both voluntary and involuntary. It stimulates metabolism as a result of powerful group contraction of muscles. The sinusoidal has largely superseded the faradic current as the physiological action of the two forms of electrical energy is similar. It may be employed in muscle testing and in all conditions where the faradic current has been found of value. This current is useful in the treatment of muscle spasm, paresthesia and for the stimulation of paralyzed muscles. The rapid sinusoidal current has given me great satisfaction in the treatment of amenorrhea. The active electrode may be inserted in either the vagina or rectum and a large dispersing electrode applied over the abdomen. I find records of six such cases treated successfully by this method.

The slow sinusoidal current is the most valuable in the treatment of muscular atony. It is of especial service in the management of abdominal ptosis. By means of the powerful and painless muscular contractions that it induces, stagnant blood may be expressed from muscles and viscera and an improved circulation and innervation are established. The abdominal muscles are developed and strengthened together with improved gastrointestinal function.

Space will permit of but a brief résumé of the most valuable of all electrical modalities made use of in medicine, viz., the high frequency current. What is known as a high frequency current is a form of electrical energy having a voltage of from 6,000 to 100,000 volts. It is an oscillatory current that changes its polarity from 800 volts to 1,000 alternations a second. When these currents of high voltage and frequency pass through living tissue a tremendous resistance is encountered and the greater portion of the electrical energy is converted into heat. It is thought that the therapeutic effect of these currents is due largely to this penetrating heat or what is known as diathermia. By means of diathermia we are able to raise the temperature of the whole or any portion of the body. Ordinary heat such as fomentations, dry heat and electric pads when applied to the body is mostly absorbed by the skin and superficial tissues. Little penetrates to the deeper structures.

If the two electrodes of a diathermic apparatus are applied to either side of an egg, it will be found, if sufficient current is employed, that coagulation will first begin at the centre of the egg.

The physiological effect of diathermia is then largely due to the effect of this heat directly transmitted to the deeper structures of the body. It stimulates the vasomotor mechanism inducing a hyperemia. As a result, spasm and congestion are relieved, circulation improved, tissue changes rendered more active, and a more normal metabolism established. An active leucocytosis is induced by means of which local infections are combated. From this résumé of its physiological action we would expect this method of treatment to be of value in the treatment of arthritis. I have found it beneficial in the management of acute infective, arthritis, synovitis, sprains and contusions, and of great palliative value in the treatment of hypertrophic arthritis. In acute sacroiliac strain and trauma about the fifth lumbar vertebra it is of the greatest value. Sciatica as the result of sacroiliac strain and of the socalled idiopathic variety, has almost invariably responded to this treatment. Some cases of bursitis have yielded to diathermia, but in the treatment of this affection I have found that the high candlepower radiant heat lamp followed by the ultraviolet quartz lamp to be of greater value.

In selected cases, diathermia may be of benefit in the treatment of neuritis. Many times after the focal infection responsible for the neuritis has been removed, the pain persists. In this class of cases diathermia preceded by radiant heat will almost always effect a cure. In pelvic congestion and dysmenorrheas diathermia is of great value. I have treated several cases of socalled chronic appendicitis with fixation of the cecum by this method. The result was in some instances gratifying. Repeated fluoroscopic examinations in three cases of this type demonstrated a marked increased mobility of the cecum.

I have found this method of value also in at least symptomatically relieving patients suffering from adhesions about the pylorus and gallbladder.

After twenty years' experience in the treatment of arterial hypertension by means of high frequency currents, I am convinced that it is the safest and most efficient therapeutic method in our possession. We recognize that arterial hypertension is but a manifestation of some underlying cause such as nephritis, syphilis or an endocrine disturbance. Diathermia will not cure nephritis, or syphilis, but it will improve metabolism and modify the vasomotor control of bloodvessels. I have found this method of the greatest value in the management of vascular hypertension so often present at the time of the menopause. This class of cases will almost always respond readily to this treatment.

Another form of high frequency electricity known as the vacuum tube discharge or what is called the violet ray, has been found most valuable in the treatment of acute adenitis, in the abortion of boils and carbuncles, in the management of acute pelvic inflammation, irritable spine, atrophic rhinitis and some forms of neuritis.

It has been impossible in this short paper to give more than a most superficial and incomplete review of the effect and therapeutic application of the various physical methods made use of in medicine.

608 East Genesee Street.

The Problem of the Physiotherapy Aide*

By A. B. HIRSH, M.D.,
Chief of Physiotherapy, U .S. Veterans' Bureau, District No. 2,
and
EMILY WELLINGTON,
New York,
Chief Aide, Physiotherapy Clinic, Grand Central Palace.

Modern physical treatment methods have taken on a new importance since their value was proved on so wide a scale in World War hospitals (1). At that time medical officers found the number of patients needing such treatments to be so great that it was impossible to give them personal attention. Technicians were found a necessity for this purpose, and so the conception of the physiotherapy aide came into being. Where to find a corps of young women, however, who would be capable of undertaking this work was the next problem. A coast to coast canvass of women's colleges was determined upon and, as a result of this effort, some five thousand undergraduates and their instructors patriotically volunteered their services. About nine hundred of these alert students passed the required tests and were given intensive three months' courses of didactic and clinical training at designated centres. Corrective exercises, massage and, especially, modern electrotherapy were taught them by eminent specialists. The service rendered our war invalids by these high type young women elicited the admiration of everyone with whom they came in contact.

Unfortunately, the uncertainties of the transition period between Army control and Veterans' Bureau management of hospitals and clinics for exservice men forced a majority of these able physiotherapy aides to change to similar duty in a civilian capacity or to return to their other prewar callings. Some, deeply interested, have remained steadfast and are giving physiotherapy applications in the government's various medical services.

Present day needs of the Army are furthermore being supplied by graduates of the yearly training courses for such aides at Walter Reed General Hospital, Washington; of the Navy, through brief courses at Brooklyn Naval Hospital, New York; of the Public Health Service and the Veterans' Bureau, by engaging the services of former Army aides and of graduates of several schools of physiotherapy conducted by medical specialists.

In the various government activities the duties of a "reconstruction aide (physiotherapy)," according to the requirements of a United States Civil Service examination, call for "administering of treatment of physiotherapy in its several branches—massage, electrotherapy, hydrotherapy, mechanotherapy, thermotherapy; active, passive, resistive and assistive exercises and remedial gymnastics; keeping daily record of the work and progress of each and every patient coming under direction and treatment; making the required reports of the activities of the reconstruction work in physiotherapy." It may be added here that the present shortage in the available supply of aides has done away temporarily with a formal examination; a written request for a socalled rating with the application for appointment, attaching written proof of qualifications, will suffice at this time.

Veterans' Bureau regulations classify aides according to the size and needs of a clinic, whether in a hospital or outpatient: Staff aides apply the actual treatments, with head aides in charge of the various separate rooms of a clinic. The chief aide, usually stationed in the office of the clinic, is responsible to the physician in charge for efficient conduct of the subordinate personnel, including the keeping of systematic records, while an assistant chief aide is at times required for close contact between the chief aide in the office and those in the treatment rooms. This organization, the outcome of past experience, leads to care in applying the various modalities and to economy of time and efficiency in general.

---

*Read before the New York Electrotherapeutic Society, May 2, 1923.

The outlook for the mentally alert, well instructed aide, physically strong and of good personality, is an encouraging one, and must improve with favoring medical sentiment. Not alone the physician in private practice, reading aright the signs of the day, must add this useful help to his office personnel but many hospital staffs also begin to realize that the lay public insists on relief through these methods as applied by the trained aide. Large industrial corporations in growing number include physiotherapy with their other means for treating injury, relieving pain, and shortening periods of disability. Almost three times as many accidents occur annually in America's workshops as were treated for our army's actual year of fighting in the recent war, so that the need for an evergrowing force of these aides at industrial hospitals and at state compensation board clinics can easily be realized. Such demands have until now absorbed nearly all available trained personnel in this field and it is only a matter of brief time before the call must exhaust the present supply.

Quite naturally such a prospect will lead many young women to grasp the opportunity, and here the question of adaptability is of first importance. What are the qualities essential in an aide for success in such physical treatments?

Unlike the oft quoted poet, the ideal aide is not born but has developed from a variety of experiences, always with the background of a mentally and physically vigorous heredity.

After a personal acquaintance with perhaps three hundred reconstruction aides, it seems that certain factors would account for the efficiency of those successful in this calling:

Public school education gives the necessary contact with the many varied types found in American households; it engenders a sense of pride in ability and softens rough edges caused by being one of a small family or having had too sheltered a childhood with, perhaps, selfish habits. The team or group feeling is developed, one particularly needed by girls, and one of which the Camp Fire and Girl Scout movements make a special point.

A collegiate course is of importance, with scientific branches as majors. Dr. Wilbur (2) rightfully maintains that a two or three years' college education, as a minimum, should include a knowledge of the fundamentals of biology, anatomy, histology, physiology, bacteria and their connection with disease, chemistry, physics and psychology.

The first socalled professional step is attendance at a normal school for physical education. Unless previously obtained, minimum instruction calls for practical knowledge of the following subjects: Physiology, anatomy, kinesiology, chemistry, histology, massage, applied anatomy, medical gymnastics, physiology of exercise, psychology, child study, hygiene, history of physical education, voice training, military tactics, dancing, play ground athletics and track work. These should be taken up seriously and not as a secondary interest to social or home interests. An active part in the life of the school will be found an advantage later on as it helps to make a girl able to adapt herself to circumstances as they arise, and to carry out her responsibilities.

Then comes training in the technic of physical therapeutics: Aside from such instruction imparted by several leading physicians who are recognized specialists in this field, the writers have knowledge of only two centres, under proper control in the United States, where systematized courses are given to those who plan to be physiotherapy aides in civilian life. A teaching course must, however, ultimately become part of staff duty at every high class hospital, being just as essential as its nurse training school.

One or two years' hospital experience, as a volunteer or a pupil or an assistant, is necessary to get an idea of hospital etiquette and to become used to the viewpoint of the physician. The spirit of cooperation with the ability to follow directions in detail is greatly appreciated in any organization. This is particularly true in a clinic giving many treatments of short duration that require special technic.

New England's profession has for a generation led the country in recognition of the worth of physical therapeutics, and again it is first to offer postgraduate instruction for aides. This refers to the course given in July and August at Harvard University. For the purpose of individual instruction thirty applicants, only, can be accepted. Its program includes six weeks' intensive training in the theory and practice of the various branches of electrotherapy and hydrotherapy, massage, therapeutic exercise in lateral curvature, posture training, relaxation and rhythmic exercise in cardiovascular disease and exercise therapy in brain and cord lesion types of paralysis, kinesiology and muscle training in the aftercare of infantile paralysis.

Now as for the patient and the aide: It is useless to expect good technic from one who has not had a scientific background. Hard and fast rules cannot be laid down as almost every patient presents an individual problem, and intelligent treatment is that which is adjusted to his needs. To a considerable degree an aide can affect the mental attitude of her patients, improve their morale and have a distinctly favorable influence by showing her personal interest in their welfare. Understanding the psychology is most important; so, also, must she show toward him the intelligent, scientific interest that is due him. Every aide must be able to note any significant change in her patient's condition, reporting the same to the one next in authority. The presence of foreign bodies or important changes in a bone condition can often be detected, so that preventive measures may be used and operative procedures averted.

Where the size of a clinic requires this executive, a chief aide can do much to make it function properly. A successful chief aide is one who knows how to tactfully place responsibility on each aide and notice which one is capable of rising to this opportunity given her. A spirit of helpfulness rather than criticism should be the rule to ensure efficiency. Each worker should be made to feel a personal pride in the clinic in which she works, keeping it in orderly, organized, running condition by attention to routine details.

As for salaries in the Public Health Service the reconstruction aide (physiotherapy), receives $720 to $960 a year and in addition appointees will be allowed quarters, subsistence and laundry and those whose services are satisfactory may be allowed the increase granted by congress of $20 a month. In the Veterans' Bureau the reconstruction aide (physiotherapy), is paid from $1,680 to $2,500 a year; the reconstruction pupil aide (physiotherapy), $1,000 to $1,400 a year. Where quarters, subsistence and laundry are available, a deduction of $600 a year will be made from the salary to cover same. In civilian practice these figures are usually higher.

This fragmentary paper would be incomplete did it not condemn socalled schools of physiotherapy conducted by nonmedical, commercial individuals engaged in pouring out a stream of graduates with wholly inadequate training and clinical experience. The physician should be just as particular in learning the source and extent of training of an aide as a prospective assistant as he would be in placing the status of a medical newcomer.

In a physician's private practice, in a hospital ward or in small clinic the most efficient results follow application of the various needed physiotherapy modalities to the patient by the same aide from visit to visit. By thus singling out the case the aide's interest is aroused to speed the sufferer's progress toward maximum improvement. When, however, the handling of numbers in a large clinic is faced, a wholly different situation must be met: Here the frequent long delays to aides, due to overlapping of treatment periods of individual patients at certain instruments, cause such a needless waste of time that the entire program of the clinic is often disrupted. The experience of such service in some of our largest war hospitals finally resolved itself into a full day treatment schedule for each aide. Each of the usual day's seven hours is divided into approximately twenty minute periods for a modality per patient. The same apparatus or modality is conducted by a certain aide for the half day, rotation in all modalities being the rule for all aides in the clinic. The patient begins with, say, a hydrotherapy or a radiant light period under one aide; passes on to another aide for twenty minutes, of, say, massage and corrective exercises; then concludes the visit by, say, a twenty minute period of some form of electrotherapy. This ideal arrangement permits of fractional times for actinotherapy and other treatments, and longer periods or additional ones for other needed modalities. It avoids the needless waste of time in a crowded clinic where one aide would follow a patient from apparatus to appartus; it greatly facilitates service for a much larger number of patients; keeps the aide in touch with all modalities; cuts down the ultimate treatment period and the resultant overhead expense.

CONCLUSIONS.

1. The fully trained physiotherapy aide is an essential of present day medical practice.
2. The required training should include collegiate study followed by a course on physical education as a preliminary to one in physiotherapy.
3. The two latter courses should be given only under medical direction.
4. Treatments given by the aide should be prescribed invariably by a physician fully trained in these methods, and her technic frequently inspected by him to assure the best results.

The Physiotherapy Clinic—A Necessity of the Modern Hospital*

By RICHARD KOVACS, M.D.,
New York,
Chief of Physiotherapy, Reconstruction Hospital.

Physiotherapy, this term having been generally accepted in this country, lately, to designate treatment by physical measures has come to the fore through the splendid record established in the war hospitals. No surgeon or medical man, who has worked in team with a well conducted physiotherapy department, would care to be without one these days. It is the history of all military hospitals that the return of men to the service was thirty per cent. greater than from hospitals where physical methods were not employed. Modern physiotherapy is not a specific for any one type of disease or surgical condition, but it is capable of affording the means for benefiting a wide range of conditions. It takes cases on the basis of a clinically fully established diagnosis and has a full understanding of the pathology underlying the condition. Physicians and surgeons who formerly declared that they had no faith in physical methods, mainly because they have never been taught when and how to apply them, are more willing "to be shown" now. Thousands of patients who had personally experienced the advantages of well conducted physiotherapy departments in war hospitals and numerous physicians having witnessed the results, are pleaders for physiotherapy in many communities.

The main argument in favor of physiotherapy is the economical one. There can be no dispute on the question that by the combined application of surgery and physiotherapy, the period of disability is shortened in almost every case and many patients who would have been cripples permanently and thus burdens upon the community were returned to productive work. There are about five million accidents annually in the United States, one million people disabled permanently. This alone opens up a great field for the correct application of physiotherapy, and there is everywhere evidence that insurance companies and modern hospitals are fully realizing the great possibilities in this direction. But physiotherapy is penetrating in every other department of medicine and its coordination will benefit every specialist, the internist, the neurologist, the gynecologist, the dermatologist, the pediatrist, and many others considerably.

---

*Read before the Thirty-second Annual Meeting of the American Electrotherapeutic Association, New York, September 21, 1922, and before the Brooklyn Diagnostic Society, January 26, 1923.

There is also no question about it, that physiotherapy measures are practised at present in many places more or less extensively. Some institutions pride themselves upon an elaborate hydrotherapy equipment, but have nothing else; others call a few pieces of galvanic and faradic outfit and a high frequency (misnamed violet ray) box an electrical department, others fill up space with Zander apparatus doing passives exercises only. Scientific massage, in coordination with other physical measures, is not heard of in most of these places. It remained for the experience of the war hospitals with many thousands of cases to work on to demonstrate that the best therapeutic results are achieved only by the proper selection and combination of all physical modalities. No surgeon will be willing to operate with half a dozen tools, or no internist will agree to use only half a dozen drugs, after they have seen the advantages of a full therapeutic armamentarium. Modern physiotherapy employs a wide range of physical modalities and while it is possible to a certain extent to interchange the therapeutic action of some of the modalities, as a rule each one has its definite indications and contraindications.

The equipment for a modern physiotherapy clinic should, therefore, include all of the recognized modalities, such as in electrotherapy, static, high frequency, galvanic, faradic, sinusoidal currents and ultraviolet and x rays; in mechanotherapy, massage, active and passive motions and therapeutic exercises; in hydrotherapy, whirlpool baths, showers, Scotch douches; in light and heat therapy, electric light cabinets and a full set of radiant light and heat applicators, as radiant light and heat is used as an introductory to almost every form of physiotherapy. The equipment for a modern physiotherapy department is, therefore, undoubtedly an expensive proposition on first investment, running into thousands of dollars, but it will be a useful investment.

The machinery will last for many years. The patients receiving the benefit of the physiotherapy treatment will always be willing to pay to the extent of their ability. Therefore, the physiotherapy department will be more or less on a selfsustaining basis. There is already a deplorable tendency in some quarters to capitalize the readiness of patients to pay for physiotherapy treatments. It will work a discredit to physiotherapy, if perfunctory rubbings are substituted for real massage, five minute light treatments for real heat and light therapy, and a few minutes play from a cheap high frequency box for real electrotherapy. No more patients should be admitted than there is sufficient personnel and equipment to handle them.

The success of a physiotherapy clinic depends on a full equipment and an adequately trained and supervised personnel, with a responsible physician in charge and as many medical assistants as necessary. The director of a physiotherapy department should have an all around knowledge of medicine, combined with a knowledge of the action and mode of application of the various electrical and physical methods. As physiotherapy penetrates into almost every branch of medicine, therefore, the diversified experience gained by general practice is essential training for a physician in charge of a physiotherapy department.

Since the average surgeon, physician or hospital intern has not had sufficient training in various electric and other physical modalities, the logical way of acquiring the assistance of the physiotherapy department would be to give a general order for physiotherapy and specify the results desired by it instead of trying to give an exact physiotherapy order from the outside. The order for the specified physiotherapy should be left to the physician in charge of the physiotherapy department. Therefore, orders from other departments should read as follows: physiotherapy to increase flexion of wrist, physiotherapy to relieve pain in knee, physiotherapy for eczema of hand, physiotherapy to chest for chronic bronchitis, physiotherapy to develop paralyzed muscles of right thigh and leg, and so on.

Patients should be referred to the physiotherapy department with a full account of the history—physical, x ray and other examinations done. On the other hand the physiotherapy department should not content itself by merely accepting the diagnosis sent, but in any doubtful case, make its own diagnosis.

Physicians of other departments having referred patients to the physiotherapy department should keep track of their patients and should be frequently invited to visit the department and watch and if necessary, criticize its results and should be taught to grasp the fundamental physical principles underlying the application of the various modalities. As electrotherapy and other physiotherapy measures are much more capable of explanation and visualization than many forms of drug therapy, it will not be long before physicians who formerly knew nothing about them will become actively interested. It is especially gratifying to see the eagerness with which recent graduates of medicine try to make up for the failure of their colleges to include practical physiotherapy in their course of teaching.

The actual treatment of the patients in the physiotherapy department is in most every institution usually given by trained workers. Physicians in charge content themselves mainly with the prescription and control of these treatments. Whereas before the war it was difficult to get an all around trained personnel for physiotherapy, the war hospitals have produced a new type of personnel, the physiotherapy aide. These aides were, as a rule, trained in all branches of physiotherapy and were readily absorbed after the war by many private physicians and clinics. It is regrettable, however, that with the passing out of the war hospital training opportunities, there is at the present no civilian medical institution of standing that would train such workers.

There are many masseurs and socalled physical culture workers who have acquired some rudimentary knowledge of electrotherapeutics, but in most cases not sufficient to make them dependable physiotherapy workers. There should be enough opportunities given by hospitals, dispensaries, and private institutions to train properly physiotherapy workers and enable them to work under medical direction; otherwise the public demand for physiotherapy will, and has already created to some extent, a dangerous form of physiotherapy quackery by some of these people trying to give the public what it wants, at their own responsibility. There is no reason why nurses could not be trained for physiotherapy.

A physiotherapy clinic should be open as a rule all day or at least a full morning or afternoon. It is impossible to run a physiotherapy clinic as another dispensary department for one or two hours at a time. On the average electrical machine not more than three patients can be treated an hour and one worker cannot give properly, more than three or four treatments or massages an hour. A whirlpool bath alone takes almost an hour, and so on. The average time required for one patient in a physiotherapy department, including waiting time, would be over one hour on each occasion. The length of time consummed for treatment will be well repaid by the results achieved.

In the Reconstruction Hospital of New York, the physiotherapy clinic is open from 9 a. m. to 5 p. m. every day and has an evening clinic three times a week from 6 to 9 p. m. Outpatients and inpatients receive their treatment at the same hours and there is enough personnel employed to attend to physiotherapy treatments in the wards of this hospital.

We will try to enumerate now at least some of the conditions in the various departments of medicine where the relief brought by physiotherapy measures is most marked and in which, therefore, a team work of physiotherapy clinic should be principally sought for by the other departments of the hospital or dispensary.

In surgery (1): First, fractures. The method of suspension and traction (which in itself is a physical measure), makes it possible to institute physiotherapeutic means from the very beginning of treatment. These may be carried on at the patient's bedside, with definite improvement. Radiant heat, combined with massage and early motion of the adjacent joints, acts as a restorative measure to the secondary disabilities formerly expected with fractures. In delayed unions or nonunions, the use of diathermy as a stimulant to the production of callus is well known.

In old fractures, with disabilities, such as malunion, fibrous union, stiffness of adjacent joints, edemas, hydrotherapy, massage, diathermia and static applications as the individual case will require, all are of untold value both before and after operative measures, and at times obviate the necessity of operative intervention.

For fibrous ankylosis of the joints, whirlpool baths, diathermia, manipulation and stimulation of the adjacent muscle groups, with static and sinusoidal are the safest and quickest means of restoring function.

The value of physical measures in scoliosis, flat and weak feet and other deformities is well known but not widely enough practised. Applications of splints and other mechanical appliances alone are never satisfactory. It remains for systematic use of exercise, massage and sinusoidal currents in wellconducted physiotherapy clinics to strengthen and rebuild the bony, ligaments and muscular parts.

Freeing of adherent scars to underlying structures may frequently be accomplished with deep local massage, ionization and whirlpool baths.

In nerve injuries the diagnostic and therapeutic value of electricity cannot be measured. Both before and after operative procedure the proper selection of the various modalities of electricity and massage are of prime importance. The maintenance of nutrition in the involved part, the selection of proper splintage and maintenance of posture of the part, taxes to the utmost the skill of both the surgeon and physiotherapeutist in their effort to secure the desired result. In the diagnosis of peripheral nerve injury, clinical examination informs us of the paralysis of the muscles controlling the movement of the various joints, and of the cutaneous changes in that portion of the skin supplied by the injured nerve, but it is only through accurate nerve testing that we may determine and demonstrate actual muscle paralysis or measure the degree of weakness present in a muscle. During treatment, actual nerve testing alone shows us the progress being made or the failure of nerve conduction to occur.

The value of immediate electrotherapy in sprains and strains from the onset of the injury, is in hastening the processes which under rest and immobilization occur only very slowly. Radiant heat and static wave current, at first gentle and later vigorous massage, so modifies the period of disability that immobilization can usually be dispensed with.

In no condition is the value of physiotherapy more clearly demonstrated than in the treatment of the frequent and difficult condition of osteomyelitis. Following the removal of sequestra, the usual sluggish reparative process is remarkably stimulated by whirlpool baths or radiant heat or ultra violet radiation, and the secondary contractures and stiffness of adjacent parts prevented by heat and electricity.

One might go on almost indefinitely illustrating various other types of cases which might benefit through the coordination of the available physiotherapeutic and surgical measures.

When it comes to border line cases between medicine and surgery, myalgia, myositis, neuralgia, neuritis, lumbago, and other conditions, the relief by properly applied physiotherapy is often instantaneous. Radiant light and heat, massage, static current or diathermia are the modalities to be used. Arthritis in its acute and chronic forms of traumatic and toxic origin is being treated with excellent local results by radiant heat, diathermia, and static wave and sparks. Electric light baths and autocondensation will aid as constitutional measures for keeping up the patient's elimination. Mechanotherapy and massage will help to mobilize the stiffened joints. Of purely medical conditions, chronic bronchitis and certain forms of asthma will yield satisfactorily to the employment of radiant light and heat to and diathermia through the chest. Pleuritic pain, intercostal neuralgia, herpes zoster can be relieved, rapidly, by radiant light and heat, static current, ultraviolet light, or static brush discharge.

Atonic forms of constipation can be gradually and surely improved by the application of sinusoidal currents. Lax, flabby abdominal walls, local and general accumulations of fat can be safely restored by the combination of radiant light and heat, passive ergotherapy in the Bergonié chair and massage. The same apparatus will greatly help to restore circulation in cardiovascular cases, while cases of myocarditis will be favorably influenced by diathermia applied through the cardiac area. Vibration of the cardiosplanchnic centres, at their exit spaces through the spinal foramina, has given remarkable results in some cases.

The neurologist will find the help of electrotherapy, massage and exercise invaluable for the restoration of function in infantile paralysis and peripheral nerve lesions. Contrary to popular belief functional cases of nerve diseases do not constitute the main playground of electrotherapy. Electrotherapy should be used with brains, and not for brains. Cases of neurasthenia, hysteria, and sleeplessness are, however, favorably influenced by these measures, if combined with proper constitutional treatment. Neuritis will yield to physiotherapy, if at the same time the exciting cause can be removed. Eminent gynecologists have published recently their favorable experiences with electrotherapy in infantile uterus sterility, amenorrhea, endometritis. The galvanic current, ionization, and in cases of infantile uterus, subsequent sinusoidal applications will be the modalities used. Spasmodic dysmenorrhea will yield to static wave applications through a rectal electrode.

In the male, cystitis, epididymitis, prostatitis, can be very successfully treated with diathermia and static wave current. Anal fistuli and hemorrhoids can be dealt with painlessly by ionization and surgical diathermia. Hydrotherapy is a most valuable adjunct in dealing with the various sexual neuroses. Finally, in dermatology, acne will be favorably influenced by ultraviolet radiations or high frequency sparks; alopecia is amenable to ultraviolet rays; ulcers, small growths, phlebitis, are readily treated by high frequency sparks or desiccation and static brush discharge. The wide range of x ray therapy in skin conditions is too well established to necessitate more than mentioning.

CONCLUSIONS.

There is an undoubted necessity for a physiotherapy clinic in every modern hospital and dispensary. Physiotherapy is a specific only in a limited number of cases, but of great benefit in a vast range of surgical and medical conditions. Recent investigations of all New York hospitals and dispensaries (2) have shown that most of them had some physiotherapy equipment but less than half a dozen had one that would constitute a full modern physiotherapy department. Similar conditions prevail undoubtedly in other large American cities. Boston is the only city that has a fully equipped and well run physiotherapy department in a municipal hospital. It is to be desired that all hospitals and dispensaries claiming to offer their patients all modern means of restoring health and working ability should organize as soon as possible a physiotherapy department in the modern sense, which means full equipment, fully trained personnel, and physicians fully understanding how to prescribe and how to use electrotherapy and other physical measures, in cooperation with the hospital staff.

The Urgent Need for a Greater Use of Physical Therapy by Internists*

By JACOB GUTMAN, M.D., Phar.D., F.A.C.P.,
Brooklyn,
Director, Brooklyn Diagnostic Institute.

In what I have to say I shall be obliged to criticize an attitude and a practice which is almost universal among internists. The attitude which I censure is one of indifference, and the practice that of neglect maintained toward an invaluable remedy—physical therapy. By this neglect we internists are doing great harm both to ourselves and to our patients. We are allowing many of them to become permanent invalids, when by appropriate physical therapy they might be restored to health and so saved from the physical, moral and economic evils of incurable disease.

Lack of special endeavor to prevent patients from remaining chronic sufferers and perpetual burdens to themselves and others, is much more common among medical practitioners than surgeons. As you know, this is becoming strikingly evident in hospitals, where, if we are open-eyed and open-minded, we must concede that surgical cases, acute and chronic, are the best provided for. Hospitals and sanitaria are always willing to admit an operative case; every facility, every comfort, every possible requirement is at hand for its care and consideration. Every practitioner who is more or less familiar with the use of surgical instruments is willing to serve and anxious to please a patient who is presented as an operative case; for these are always interesting, usually not protracted and thus not taxing to the patience of the surgeon; the results are immediate, the changes often profound, the patient and friends are grateful; hence, the remuneration, material and professional, is generally satisfactory.

But what about the medical case? Those of an acute character, at least, are given some attention, though less than surgical cases. They are admitted to hospitals quite readily, and in so far as they require only medication and nursing, proper care is accorded them. When, however, the case is a chronic one, the situation is then altogether different. It is here that numerous sins are committed, that unpardonable errors are made. Of course it is true that chronic cases are often tedious, usually uninspiring and discouraging, the best efforts of the practitioner being frequently unappreciated. Nevertheless our duty toward the chronic sufferer is no less stern and unrelenting than to the acutely ill patient whose life we are striving to save by all the means at our command. We are in duty bound to use no less effort in the treatment and rehabilitation of chronic than of acute sufferers. The use of pills, lotions, kind words or patting on the back does not always help in chronic diseases, for these are characterized by actual morphological and chemical tissue changes which may require radical, rational and appropriate intensive therapy to effect a reversion to the normal. And how do some practitioners meet the situation? Do busy physicians always give such patients the necessary care and deliberative attention? In many instances, no; seldom is there even a thorough analysis given the patient, who receives merely a prescription, accompanied by a few useless recommendations which naturally afford no relief. Later another, a third and a fourth ineffectual remedy is prescribed, until the patient tires and seeks help from other sources. Such sufferers constitute a vast army and their number will not diminish until we have recognized the cause of their defection and shall have included in the regular medical practice a more extensive use of physiotherapy.

---

*Read at a Symposium on Physiotherapy, Brooklyn Diagnostic Society, April 14, 1922.

HISTORICAL.

In so far as the remedy for this lies in a greater use of physiotherapy, we are not dealing with a new method of alleviating suffering, but with one that is old and well tried; for physiotherapy is the oldest of medical disciplines. Centuries before man made an attempt to free himself from discomfort and pain by the use of drugs, physical means were in use. Lower animals are led by intuition to seek relief from pain and sickness by resorting to heat, cold, friction and similar physical methods. Such tropismatic and semitropismatic tendencies were evidently inherited by our early ancestors. The study of primitive man and of the distant past shows that at the lowest known culture levels men possessed the knowledge of heat and cold, of rubbing, of baths, of mineral waters, of emetics and purgatives, and that they utilized their knowledge in the bringing up of their young, the development of their bodies in strength and skill and in the treatment of disease. As long as primitive man followed his natural instinctive trends he could not go wrong, but in this, as in other provinces of man's life, his newly acquired, imperfect thinking powers have led him astray from his true, natural course into new, injurious and irrational ways. Professional wise men, shamans, sorcerers, priests and other manipulators and promoters of medical dogmas diverted medical practices from the simple, inherent reactions of animal behavior and replaced them with strange, distorted and gruesome rites. Even in the earliest times, medicinal waters were placed under the patronage of divinities and were subject to occult influences. Prayers, incantations, charms, ridiculous and repulsive substances were held to reinforce the effect of heat and cold, of baths, of friction, of waters, etc. For instance, the pool called Bethesda (1) at the sheep market in Jerusalem, was healing only to the one who entered it after the waters had been troubled by an angel. Religion was injected into the science and art of healing at every low cultural epoch.

At a later period, in Greece and Rome, bathing, gymnastics, diet and massage were prescribed, not only for the development of sound, healthy and skillful citizens, but also as therapeutic measures for strengthening the body and promoting health. The temples of Æsculapius distributed throughout Greece were genuine sanatoria. They were situated in sacred groves, near mineral, thermal or sea water, in sheltered regions. They were in the hands of hereditary priests, but these, fortunately, seem to have realized the connection between natural therapy, moral influences and physical development. Hippocrates thoroughly understood the value of air, food, rest, exercise, sleep, the rôle of the excretory processes, of psychic conditions, weather and seasons, and laid down the simple, rational rule—which is even today often disregarded—that "If excessive fatigue has induced a disturbance, rest is required; if, on the contrary, it is the result of inactivity, it is exercise that must be employed." Credit is also due him for being the first to declare that cold water warms the body and hot water cools it. He recommended hydrotherapy in a great many conditions, and so much was he impressed by its importance that he held it to be a physician's first duty when first coming to a town, to become acquainted with the peculiarities of the water in any town to which he went. His methods of administering cold baths, of rubbing, and showers were carried out by his disciples and his many dietetic regulations survived for a long time.

Roman medicine, which was in a state of gross superstitious barbarism before the conquest of Greece, quickly felt the influence of Greek civilization. Gymnastics, massage, diet and hydrotherapy replaced the crude practices of the pre-Grecian period. Public baths were soon built in all Roman settlements; wonderful establishments were then provided for gymnastics, baths and social entertainments; mineral waters and hot springs became esteemed. There are still in almost every famous health resort of Western Europe the remains of Roman baths, some of them, such as the ruins at Bath, England, showing evidence of magnificence.

Arabian medicine, which weakly bridged the gulf between the Greco-Roman and Renaissance periods, was timid and especially reliant upon drugs. During the Dark Ages systematic care of the health was not only made difficult by the prevailing degradation of all the arts of life, but the most influential intellectual forces of the time were opposed to all solicitude concerning the body. But with the beginning of the fifteenth century, physical therapy regained some of its favor, and even charlatan surgeons began to use water in the treatment of wounds. In the sixteenth century Ambrose Paré observed, at the siege of Metz, that an ignorant empiric who treated wounds with water, lint and incantations, had good results. Paré began to treat wounds and fractures with cold water, saying: "I declare it is not the words nor the cross which do it, but the water which cleanses the wound and protects the injured limb from inflammation and the contact of other fluids by its coldness," and he gave up the use of hot oil in dressing wounds.

During the sixteenth, seventeenth and eighteenth centuries, physical therapy had several periods of popularization and decadence. Thus, at one time the public baths were altogether closed for a long time because the spread of syphilis among the people of Europe was attributed to their use. On the other hand, in Germany, since the seventeenth century, hydrotherapy has often been considered a panacea for the cure of chronic and acute diseases. There it has received its greatest impetus, and there the cure of chronic diseases seems to have advanced further than in any other part of Europe.

If we compare the progress of applied physiotherapy during the past century and a half with that of other branches of therapy, we note that in spite of the considerable advances in the latter, the advance of healing by physical methods has remained relatively low. And why? Because intense individualism was characteristic of that period. Professional education then became largely an affair of apprenticeship; young men read law or medicine while they were acting as clerks or janitors in the offices of their masters. The functions of the State were reduced practically to police measures; every State undertaking designed to improve the conditions of suffering humanity, met with tremendous opposition; free schools, free textbooks, public baths, state hospitals, were regarded as instruments of decay, calculated to undermine personal initiative and independence. Individual responsibility was the religion of the time and hardly any rational limits were set to its scope. Thus progress until the present decade was slight.

PHYSIOTHERAPY AND THE WAR.

Opportunity was provided by the late war for an immense and illuminating demonstration of what physiotherapy may accomplish. The materials were: 1, vast numbers of wounded coming from every front; 2, powerful motives for returning the disabled to their armies with a minimum of delay, and, 3, the great unstinted resources of governments. The results achieved in hospitals and reconstruction camps during and since the war may appear to some like a marvelous new development. But in reality it was not a new development at all; it was only a great scale repetition of what had already been accomplished in a smaller way. It should not be overlooked that ardent and expert physiotherapeutists already existed and that they were eager to do for large numbers what they had already been doing for the few. Physiotherapy aides were, indeed, trained during the war, but the immense service rendered to the wounded and disabled soldiers by the application of physical remedies was due to those faithful enthusiasts who had already, before the war, brought physiotherapy to a high standard of perfection.

In the German army this fact was brought out sharply. It was there that the first and very intensive application of physiotherapy was made. This was natural, inasmuch as in Germany physiotherapy had already occupied a position of greater importance than in other countries. Since the inauguration of the Bismarck socialization measures, many state subsidized sanatoria, socalled *Kurorte*, have employed physical therapy almost exclusively. These large, wellequipped institutions with their trained staffs have taught the whole German medical profession the resources of physiotherapy. Hence its general and instant application in the German army. In the armies of other nations it took some time to familiarize their medical corps with the resources and advantages available in physiotherapy before these could be made fully available in the treatment of the disabled soldiers.

STATISTICS.

A small fraction of the remarkable results obtained by means of physiotherapy, both in military life during and after the war and in civil life in industrial institutions, is illustrated by the following statistics:

Granger (2) writes: "In the army ninety per cent. of all cases treated by physiotherapeutic means were able to resume their former or allied vocations. Two points in this connection should be noted; first, there was a marked shortening of the time of disability; second, many who otherwise would have been permanently crippled and would in consequence have been a burden to the community, were returned to productive and remunerative occupations. The economic gain resulting from these two factors means a marked saving to the industries, to the insurance companies and to the individuals who have been incapacitated." Mauclaire (3) reports that in France physiotherapy was used for functional reeducation at fifty-three centres upon 22,000 wounded soldiers, of which 19,000 or eighty-six per cent. were returned to their respective occupations. Sammons (4) states that in his injury cases treated by physiotherapy the results in eighty per cent. were all that could be wished for; of the other twenty per cent. in which nerve anastomosis were followed by a full course of electricity, massage and hydrotherapy, only a small fraction remained unimproved. Burke (5) in his report on the electrical department of the Horton War Hospital, states that of the 958 patients treated there, about thirteen per cent. were cured, twenty-four per cent. much improved, sixty-eight per cent. fairly improved and only five per cent. unimproved. The number of complete recoveries, he says, was undoubtedly greater than the percentage specified, as many of his socalled improved cases were transferred to other institutions before their complete cure could be effected. Raynal (6) studied 504 histories of soldiers with wounds of all types and degrees of severity, affecting every part of the body, who had been treated by physiotherapy. He found that thirty per cent. were cured, sixty-two per cent. improved and about eight per cent. unimproved. Fox (7) emphasizes the importance of prompt treatment before physical and psychical habit has reduced the chances of cure; he gives the following statistics: Out of 3,348 soldiers suffering from disabilities of all kinds, who received a full course of treatment and were discharged from the hospital within six months, 2,676 or about eighty per cent. were cured or so greatly helped as to be returned to their depots; 457 or fourteen per cent. were recommended for auxiliary service, while only 215 or six per cent. had to be discharged from the army because of disability.

In the Anglo-Belgian hospitals at Rouen (8) 2,020 soldiers received physical therapy; of these 1,170 or nearly fifty-eight per cent. were sent to rejoin their depots as completely cured; 670 or thirty-three per cent. were recommended to the military institution for industrial training; only 180 or nine per cent. had to be returned to their homes as invalids. Figures have been published in France which show that an average reduction of the mass of physical disability—say twenty per cent.—saves the State in pensions and gratuities nearly fifty million francs yearly. The saving that is accomplished by the return of the men to industrial life is, of course, immensely greater than this sum.

Finally, Major Charles P. Hutchins (9), after describing the reconstruction work done at Fort Sheridan, says of physiotherapeutic measures: "By right of accomplishment in a hundred thousand cases of war illness and injury alone, they have won their place in the regular curricula of medical pursuits."

Industry, alive to the importance of restoring health whenever it constitutes a reduction of expense, is already becoming the next large beneficiary of physical therapeutics. Many employers, having learned their lesson from the governments, have established physiotherapy departments in connection with their industrial institutions or hospitals and afford physical treatment to their injured or maimed, thus benefiting themselves and their employees. As an example of how physiotherapy serves industrial medicine, Wainwright (10) publishes a table showing the length of time of disablement in uncomplicated simple fractures in two groups of mine and railroad employees, treated before and after the installation of a physiotherapy department. There were about 125 men in each group.

	Before	After	Saving in days	Percent imp'ment
Clavicle	67 days	59 days	8	12
Humerus	125 "	90 "	35	28
Radius, ulna or both.	76 "	64 "	12	16
Femur	239 "	180 "	59	25
Tibia, fibula, or both.	121 "	92 "	29	24

The saving effected in this small group is given as about four thousand dollars a year, which, of course, means only a direct saving in compensation; the ultimate benefit to society can not, of course, be estimated in dollars and cents.

The conclusion one must draw from these few statistical data—time and space not permitting greater expansion—is that an unbelievably large percentage of cripples of all kinds, in military and civil life, with injuries and disabilities of every degree of severity, have been through the use of physiotherapy, either completely cured or nearly so, and that these cripples were returned to their homes, families and countries happy and useful citizens, whereas without the benefit of physical therapy they would have remained cripples, a burden to themselves and to society. What other means of therapy, not even excepting surgery, can boast of so marvelous a showing!

OBSTACLES TO GREATER EXPANSION.

But has the medical profession or the general public benefited by this demonstration of physiotherapy? Apparently not yet. The remarkable reconstruction work which effected such brilliant results has not been continued in civil life because, as Cotton (10) says, of lack of teamwork between surgeon, neurologist, internist and physiotherapeutist. There are also many other factors which appear to be against a general expansion of physiotherapy. In all institutions caring for chronic, disabled invalids, there is a lack of appliances, and before the civil population as a whole can be given the benefits of physiotherapy, greater facilities must be created, not alone in equipment but also in personnel. Physicians here must overcome the apathy which has left us so far behind the foremost European countries; they must overcome the unwarranted distrust of the pioneers who have the courage to practise physiotherapy. The rejection of curative agents solely because these have been tools of charlatans is a remnant of timid orthodoxy which has too long fenced us off from one of the most fertile fields of medicine. This timidity has been essentially overcome by some surgeons; the fair-minded surgeons, as Snow (11) points out, are now becoming less antagonistic to physical therapy because of their knowledge of its possibilities, first acquired by them during their service in the war. On the other hand, grasping surgeons—and they constitute no negligible number—are still hostile toward it. There is, however, no doubt that the physical therapeutist will soon be part of the staff of every busy surgeon or institution. Billings is convinced that every hospital needs a physical therapeutic department just as much as an operating room. Certainly no institution which undertakes to treat chronic diseases or industrial injuries can produce first class results within a reasonable time without provision for such work, and it may be presumed that within a short time no such hospital will be able to face its community and confess that it has not made such provision (Cotton, 12).

Before a full and extensive use of physiotherapy can be made, there must be a spread of special knowledge of the subject. Fruitful and safe work in physiotherapy, as Sampson states, renders necessary the correct selection of appliances and an accurate application of their modalities. Inaccuracy or improper modality is fatal to success. Investigations have been conducted in physiotherapy to determine the doses and methods applicable in certain definite pathological conditions; ignorance or neglect of these scientific physiotherapeutic data must result in failure as surely as the improper use of drugs. The therapeutist, before he can achieve good results, must be thoroughly familiar with the potentialities and modalities of the numerous physiotherapy appliances. Physiotherapy is a skilled art which calls for both training and natural aptitude.

The difficulties which exist on the score of expense are also at present momentous. And even if the cost of equipment had not to be considered, the sum required for the maintenance of a physiotherapy department might be regarded by some as prohibitive. But this should not even for a moment come into consideration when the welfare of the patient and the community is at stake. Besides, on the ground of economic expediency, a department of physiotherapy is a profitable investment, yielding large returns in the saving of labor power and the reduced force of caring for the incapacitated, as well as the moral and esthetic satisfaction that accrues from all successful efforts to minimize sickness and disease. When its great and manysided usefulness is once recognized, its cost would no longer be considered, and large scale provision for physiotherapy would come to seem as indispensable as provision for operating rooms and extensive diagnostic equipment seems to us at present.

Wilful neglect of physiotherapy by internists, or of rehabilitation and vocational training, is incomprehensible in view of what these have lately accomplished; for the internist to go on ignoring agencies with such a record of beneficence is inexcusable folly toward himself and cruelty toward his patients. It is not asserted that physiotherapy is either a panacea or an exclusive remedial procedure. In chronic diseases, especially, every possible curative means may be required, for in these cases excretion, metabolism, circulation and endocrine functions may all need restoration, balancing or stimulation. Any and all remedies may be applicable, and the physician should be at liberty to use them all; they are his rightful tools, and he should not permit them to be usurped by any cult or schism. Nevertheless, physiotherapy holds a unique place among the other remedies because it permits of many applications and comprises many means for helping to restore abnormal conditions to normal. Its use, in the main, develops forces which stimulate life processes—forces which in normal health are competent to increase strength and vigor and in subnormal or abnormal health act by the same dynamic mechanism on the cells and tissues, exalting, depressing or transferring their energies in ways which increase benign and diminish vicious activities. All in all, its value is so great that any medical man or institutional group who accepts the responsibility of treating chronic disease without making provision for physiotherapy, is committing an injustice to the patient, the community and the medical profession. Failure to provide such therapy fosters pseudoscientific practitioners, strange cults and weird healers.

My personal experience with physiotherapy dates back to about ten years ago, when, during a prolonged stay abroad to study diagnosis and institutions, I had the opportunity to familiarize myself with its great possibilities. The extensive equipments of the sanatoria which I visited in Austria and Germany, their trained personnel, the strict regimen and regulated tactics, and their results, more than sufficed to impress me favorably. Physiotherapy is the basis of the successful treatment of chronic diseases abroad and of the conspicuously small number of operations. Sun baths, mineral spas, Zander institutions, inhalatoriums, and other institutions, are features of all healing places throughout Germany and Austria. There, marvelous results are often achieved in cases which in this country would either be subjected to some exploratory operation or be classified as incurable and condemned either to endless suffering or allowed to fall into the hands of quacks.

The application of physiotherapy to medical cases is unlimited. Among those suitable for treatment may be mentioned obesity, hypertension, nephritis, neuralgia, neuritis, paralysis, gastrocoloptosis, gallbladder, catarrh, chronic appendicitis, constipation, general atonicity, neurasthenia, hysteria, tuberculosis, and numerous other chronic diseases. Many of these conditions are benefited quite as certainly as those surgical cases which have already contributed so much honor to physical therapy; and the medical practitioner, if he were wise, will make use of these physical agencies quite as extensively as many surgeons are now doing.

PHYSIOTHERAPY VERSUS QUACKERY.

Quacks are availing themselves of the riches that we ignore, and, fortified with our honorable tools, they are building socalled schools of medicine by which they prey upon a large fraction of society. Since society is an organism of which the suffering patient is a part, his failure to find relief from sickness has consequences in which we among many others are included. When the patient is of the sort that, through good or ill, never forsakes a favorite physician, one fruitless medication after another may be tried for an illness that is meanwhile speeding toward incurability, although it may not at the beginning have been irremediable. Here the evil consequences do not conspicuously affect the physician; he does not suffer in honor or profit. It is much the same case in regard to those less trusting patients who go from one physician to another; gain and loss are likely to balance, and no special discredit attaches to the loss of such migratory patients.

Far more numerous than these two classes are the patients who, discouraged with all regular physicians, seek relief through socalled irregulars. These irregulars, whatever their label, nearly always employ one or more socalled natural remedies. Their science is a smattering of physiotherapy, ignorantly conceived and ineffectually and incorrectly applied, and yet, not infrequently helpful. If a patient receives even slight benefit from one of these, he is likely to announce it with unstinted praise, and the more he had previously sought relief through legitimate medicine, the more material has he for invidious comparisons.

If, on the contrary, a patient is not benefited, or even if he is harmed, he usually conceals his adventure into quack medicine. In the first case the quack gains reputation; in the second, he does not lose it, and he exploits every success to the utmost, advertising himself by contrasting his socalled cures with the actual failures of the regular practitioner. All too often he is assisted in his selfexploitation by honest and reputable patients who have been thrust into his care by our neglect of priceless remedies, which, even in the hands of a quack, prove superior to our ineffectual because inappropriate therapy.

This is the true explanation of the great present prosperity of the pseudo-legitimate healing cults—of osteopathy, chiropractic, naturopathy, Kneipp cures, etc. On the one hand, chronic sufferers are many, and there also exists a widespread respect for those means of healing which people conceive as natural, i. e., heat, cold, bathing, rubbing, exercising, and others. On the other hand there are charlatans—also many—ignorant and unscrupulous but astute enough to give the people what they want, and with the advantage that the things desired are really good and useful when properly applied. The treatments, in part at least, are so simple and easy of application that, even when applied indiscriminately and by tyros, they produce many conspicuous cures and improvements. The inevitable result is—busy and prosperous irregular practitioners, less busy and less prosperous regular ones. To a large percentage of our profession the economic loss created by this situation means the difference between poverty and a decent competence; but even more serious are the moral and humanitarian issues involved. By unintelligent, obstinate adherence to the exclusive use of drugs and, until recently, of unassisted surgical procedures, the medical profession has not only sacrificed much honor and confidence, but has refused a legitimate means of help to that great stream of sufferers who have turned for relief to illegitimate healers, by whom, though now and then one patient is cured or his condition improved, many are irreparably damaged and almost all risk serious harm.

CONCLUSIONS.

The number of cults and charlatan practitioners, instead of diminishing, as it ought to do with the spread of education, is actually increasing. Even greater is the proportionate increase in the number of patients who resort to quacks, with the result that in this country the latter are becoming every day more numerous, more prosperous and more confident.

In European countries, where the practice of physical therapy is most developed, irregular medical practices are at a minimum. By making the fullest possible use of such remedies as baths, electricity, gymnastics, massage and sunlight, physicians in those countries deprive quacks both of the means to victimize and of the victims. With us, the internists have left to quacks almost a monopoly of physical remedies and have been supplying them with streams of victims.

For this evil the internist is not alone or is he altogether to be blamed—like most evils, its causes are complex. But on two counts at least he is guilty. First, he has kept in the easier way of drug therapy instead of working to create facilities for the use of physical therapy; and, second, he has timidly shunned the use of physical remedies simply because these were used by quacks and for that reason discredited by association.

We must recognize our responsibility for the situation which exists before we can hope to cut off from the consultation rooms of the irregulars and from the churches with healing cults, the streams of chronic sufferers. And before we can hope to command full public confidence and respect, there must be a general recognition that, though neither infallible nor omnipotent, we are doing the best we can. For it is through our apathy and timidity in surrendering to charlatans these rich therapeutic fields, that they have gained an appearance of solidity, and even superiority, which has deceived many tolerably intelligent and instructed people. We have allowed this situation to develop; we can best abolish it by making a thorough, intelligent and conscientious use of physical remedies—remedies which in spite of their neglect by the medical profession, have always retained a widespread, almost universal, respect among the people. By satisfying this legitimate, seemingly inherent desire for ways of treatment which appear natural, we can safeguard the public against malpractice and incidentally regain its confidence far more quickly and thoroughly than we can by giving time to the securing of legal restrictions of irregular practitioners and the punishment of offenders.

Electrotherapeutics in Urology

By VICTOR COX PEDERSEN, A.M., M.D., F.A.C.S.,
New York.

In the library of a New England College is a *Chemistry* of 1850 written by a man sufficiently able to have been a clergyman, writer, professor and chemist. In those days the alert mind could acquire the final knowledge of several vocations—knowledge which today belongs to the junior or senior of academic or professional school.

The opening paragraph of that chemistry states that there was then before the scientific world a theory concerning the organization of matter called the atomic theory and that for the purposes of the book the said theory would be denied and disregarded!

There is now before the scientific world a new theory concerning the organization of matter known as the electron theory. It assumes that the atoms are composed of inconceivably small electric elements —electrons. There are those who deny this theory and they will be as ridiculous fifty years hence as is the writer of the said chemistry of 1850 in the light of modern facts about the atomic theory.

Lincoln said that the only people he did not like were those he did not know. Most physicians seem guilty of the same blunder in not liking any new method of treatment which they do not know. Conservatism, reserve and caution are sound when based on a willingness to study, try and then judge. But radical denial, blind prejudice and arrogant complacency with methods already in vogue are unsound because they have again and again been the bases of cults which have in the end compromised the medical profession. Osteopathy and chiropractic would never have been dignified as separate schools if massage and its allies had been correctly valued, taught and practised.

Christian Science and its allies would never have developed if the influence of the mind on the body had been more directly observed, studied and employed.

Like Lincoln's new friends most of us like new methods after we have learned them. A familiar example is that the medical departments of the United States Services during the war actually ignored and refused to adopt physical methods of all kinds—until they knew them through their results among the European forces. The Government has learned the worth of a new friend—physiotherapy—and has installed proper equipment in many of its large hospitals. The Government was in the same position in which Morse would have found himself if he had denied the possibility of a telephone after having demonstrated his telegraph. At that time no one even conceived of a telephone. Bell not only invented the telephone but lived to see the wireless telegraph, which he might also have ridiculed if even its remote possibility had ever been suggested to him when he gave his telephone to the world. In parallel Marconi not only developed the wireless telegraph but has seen the radio come into the field of communication. Yet no one can show in any of his early scientific writings any definite statement to indicate that he realized the possibility of the modern radio.

Electrotherapy which is only one department of physiotherapy can no longer be repudiated. Those who deny that it has value will soon be like the professor of 1850 in his disregard of the atomic theory. Those who regard it as a quick cure and a cureall will be like the dupes of the promotor whose financial bubble bankrupts them. Diseases are processes hence there can be no sudden and absolute reversal of the processes by any means whatever.

Most of our methods heed basically the circulatory and nervous signs of disease. It is the stimulation or modification of circulation in acute and chronic inflammation by ingestion or topical application that aids very many mucous membrane lesions. Of great importance is correction of nervous disturbances such as pain and its allies, which alleviates much suffering, such as trophic failure which permits restoration to begin.

Bier's hyperemic treatment of joints was aimed to oversupply the lesion with blood and hence augment nutrition and healing. But its basis is a venous stasis and not arterial hyperemia—hence its limitations and early rejection. Personally I never used this method much because its venous stasis is not a physiological nutritional condition. Electricity excites contrariwise an active arterial hyperemia and thus does follow physiological conditions, as will be indicated later.

It seems probable that the electron conception of the organization of matter will be proved much as the atomic theory has been established. Rather than reject the theory it should be tentatively accepted. If it is true about inorganic matter then it is true about organic matter and if true about organic matter then it is true about the human body. Already a leading English physicist (1), in the Kelvin Lecture, states that dependent on x ray penetration and on further research of x ray frequency, the possibility is indicated of restoration by the x ray of electrical equilibrium or health in a cell structure. Whatever may finally be the actual result of Stokes's method of endeavoring to modify and aid ear conditions by fractional doses of x ray, its scientific foundation is in line with what physicists are thinking out in other fields and beginning to teach. It is equally probable that the small doses of rays administered are wrong in amount—too small or too large—and that the quality of the rays themselves remains to be changed by improved methods of developing them. For example, many electrotherapeutists prefer the x rays developed by the multiple plate high speed static machine to those developed by the transformer, for the reason that its very high voltage and very low amperage give great penetration (which is the great desideratum) and cause little burning of the skin (which is the chief danger) in x ray therapeusis. No man may say whether or not a still better source of the x rays will appear sooner or later.

Stokes in a paper read before the New York Electrotherapeutic Society on February 7, 1923, enunciates a suggestion or theory which he describes thus:

"In my research of recent years with the x ray I have assumed that electrical equilibrium, or preferably electronic equilibrium, in the human cell structure is a natural and normal condition indicating a state of health in that structure; and that any upsetting of this equilibrium except through normal physiological excitations and transmissions, means an unnatural or abnormal condition indicating disorder or disease, as the case may be. In the use of the term 'electrical equilibrium' I assume, in line with the electron theory, that all forms of matter are exhibitions of electrical phenomena.

Without going deeply into the generation of x rays, I would like to call attention to the recent important discovery of a reciprocal action when x rays strike any substance. The blast of electrons in the tube on striking the target gives over its energy to the energy of x rays, and the x rays in turn, on impact with any substance, turn over their energy into the energy of moving electrons." The process might be called also electronotropy—change in the electrons—meaning the result of so modifying the pathological state of the electrons that restoration may begin in the body cells and of so influencing the bacteria that they alter or lose their virulence. While all this is theory it can not be ridiculed and it is not in discord with the ideas in the scientific world outside of medicine. In both medical and nonmedical spheres of knowledge proof is to be developed. Since the electrons of living matter are inconceivably minute it is almost certain that very slight electric influences affect them. In other words it is not necessary to frighten or hurt the patient to do good work.

A suggestion of the truth of electronotropy is already established in that the mild currents which the patient hardly feels at all or always finds comfortable are those which do good—in direct opposition to the violent currents in vogue in medicine up to perhaps ten years ago. Lack of space prevents a further discussion of the parallel between the concept of such matters in the sciences of physics, chemistry and medicine. Electricity in medicine is not a cureall. It it fallible in almost any case. Most of its difficulties arise from defects of apparatus, selection of wrong modality, improper intensity of current, too long or too short intervals of treatment, and inexperience in the operator.

Treatments in most conditions of less than twenty minutes are not long enough and usually thirty minutes are a better limit. Hence at least three treatment rooms are required for justice to each patient and for rate of service consonant with the usual one in good work in any other special line, namely six to nine patients to the hour. Such a layout of offices is not difficult but it may be beyond the means of many. This overhead expense is a disadvantage.

The advantages are briefly that the physician alone gives the treatment and in this way controls the patient, who can not repeat, distribute or otherwise abuse the treatment as he does with prescriptions too often. With skill electricity becomes a very exact local means of hyperemia, hemostasis, contraction, and anesthesia.

The following very brief technical description of the currents and outline of their application in urology may be helpful.

They are adapted from a recent contribution (2). Any reader interested in this general subject and wishing to know the history of its progress and to understand the reasons for unsatisfactory results in the past may be repaid by reading this much longer contribution.

FARADISM.

Modern high tension coils give currents according to demand. The outer or secondary coil is the source. Fine windings of wire give anesthetic effect but coarse wire is preferred for physical effect. The markings 1000, 2500, and 5000 mean the number of feet used, according to the switch. The preference is for 1000 feet because of greater physical action. A weighted vibrator, timed to thirty oscillations a second to agree with the muscle fibrillation, is convenient. Interruptions may be made with switch or metronome, at a rate not to exceed the pulse thus permitting inflow and outflow of blood, stimulating metabolism and avoiding the exhaustion or spasm. An insulated electrode applied to the prostate and a large dampened pad to the pubic region are the best. Intraurethral electrodes are not advisable. The strength of current mildly increasing has less respect for sensation than for muscular contraction. The duration is from fifteen to thirty minutes, the frequency alternate days, and the results muscular tonicity, profound circulatory effect and relief of circulatory, glandular and tissue stasis and of muscular atony. The electrotherapeutic alternate is diathermy followed by static wave or the galvanic constant or interrupted sinusoidal current.

In modern urology the use of faradism is to stimulate the atonic bladder and sphincter, especially in postoperative states. Mild currents continued for twenty to thirty minutes are the choice.

GALVANISM.

Galvanism is a continuous positive or negative current whose polarity effects cause electrolytic or chemical change. The current is followed by nutrition or destruction depending on the strength and method. Batteries of high efficiency for the desired milliamperage are preferred unless a generator is available, free from the fluctuations of street current. The rheostat reads 0 to 20 and the milliamperemeter, from 0 to 70. Insulated electrodes are used. The negative pole (because relaxing) is in the rectum for acute conditions but the positive pole (because stimulating) is used for relaxed conditions, while a moist pad about six by four inches is on the pubic region under a sandbag. The strength is up to 10 milliamperes for acute and from 20 to 70 milliamperes for subacute or chronic conditions, beginning low and ascending, with sensations but without pain. The current should never be used without a meter. The duration is from fifteen to thirty minutes. Weak currents with maximum duration are superior to strong currents with minimum duration. The frequency is alternate days and the results are determined by the positive (acid) or negative (alkaline) polarity. The electrotherapeutic alternate is the Oudin current through the high vacuum glass electrode. The physical adjuvants are hot and cold hydrotherapy and phototherapy for circulatory stimulation or sedation on the following day as needed. Digital massage is not advisable.

Urology of today requires interrupted galvanism in prostatics: First, the relief of congestive states in nonoperative treatment or inoperative cases as an alternate or substitute for other modalities; second, restoration of postoperative atony or damage of the muscle wall and sphincter. These aims are identical with those of neurologists in the muscle lesions of neuritis, paralysis, and surgical injury.

IONIZATION AND WATER ELECTRODES.

Ionization and water electrodes belong under galvanism produced and regulated as stated under that subject. The electrodes are urethral, insulated down to the last inch. The negative of copper or zinc is placed in the urethra while the large positive pole is on the pubic region. The current (continuous, never interrupted) should cause no muscular contraction but only mild warmth under a range of from one to five milliamperes. Treatments last from five to ten minutes, on alternate days, and relieve subacute and chronic engorgement. The electrotherapeutic alternates are diathermy to increase the efficiency and the wave current to produce tissue contraction. Digital massage and hot or cold hydrotherapy are omitted. Phototherapy almost equals diathermy as an adjuvant.

In urology mild ionization is useful in granulations and edema of the prostatic urethra. The zinc urethral electrode on the negative pole is used for subacute conditions requiring relaxation and on the positive for chronic lesions requiring stimulation. Oxychloride of zinc reaches the deep tissues for nearly 0.5 cm. The current should be three milliamperes and its duration five minutes. The polarity should be reversed from the positive pole so that the relaxing negative pole will relieve adhesions and avoid trauma. Ionization should be the last modality tried by the novice after he has learned all others.

SINUSOIDALISM.

The sinusoidal current is a slowly rising and falling continuous current reversing its polarity at the end of each cycle. It alternates contraction and relaxation of both striped and unstriped muscle. The wave must agree with the heart rate for greatest benefit in the muscle substance or organs like the prostate containing muscle. The source is faradic current and galvanic current from the appliances already detailed, each being used alone or both in combination. Therefore all details are the same as to rheostat, milliamperemeter, strength of both forms of current, electrodes and their placing. The sine wave agrees with the pulse or is directly proportional therewith, such as half rate or quarter rate. The sinusoidal controller reads from 0 to 10. The strength of current is, as in galvanism and faradism, determined by the contractions, sensations and meter. The duration of treatment is from twenty to thirty minutes without weariness and the frequency alternate days. The effects of the faradism and galvanism are the same as those for each current separately except that the sine wave of the galvanic current affects the unstriped as well as the striped muscle, whereas faradism affects only the striped muscle. The physical adjuvants are hot and cold hydrotherapy and phototherapy exactly as just stated. Digital massage is not advised.

Up to date urologists may use galvanic sinusoidal in the same cases as are noted under interrupted galvanism. The sine wave corresponds very well with the manual or metronomic interruptions spoken of under galvanism.

STATIC WAVE CURRENT.

The static wave current has high voltage, initial low amperage and pulsatory effects. It is a capacity discharge of an unidirectional current, and disperses rapid electrophysical effects in the part. Contractions occur in all contractile tissue and even in cell protoplasm. The apparatus is a motor driven, multiple plate static machine of sufficient capacity, with a rheostat with many stepups and a milliamperemeter. The wave current is one of high voltage and fractional milliamperage. The electrode is of insulated metal tip prostatic type applied to the gland for the wave current from the positive pole or the high vacuum glass electrode for the actinic influence of the negative pole. The current produces contractions tolerable to the patient. The sparkings are 60 to 120 a minute. The frequency of treatment is alternate days given from twenty to thirty minutes and the immediate results are without discomfort. The electrotherapeutic alternates are the high vacuum tube and diathermy and phototherapy—the last two being similar. Digital massage, hot and cold hydrotherapy, are of doubtful value. In prostates whose acini fill up and discharge periodically, digital massage is a required adjuvant.

The static wave current has made good for about twenty-four years. The indications are not wholly standardized and authors differ somewhat in distinguishing between the static wave, static induced and high frequency current. No good classification of cases, reports of cases and cystoscopic diagnosis before treatment or after treatment are given. Hence a valid element in the diagnosis is omitted and much of the work is open to question and even rejection. In the matter of classification at least infected and uninfected cases should be recognized. The static wave current in urology is valuable for congestion, relaxation and edema of the prostate in all functional disorders associated with hypertrophy. It has no influence in true hypertrophy or neoplasm.

HIGH FREQUENCY CURRENTS.

High frequency and alternating current are synonymous terms, applied to rapidly oscillating current converted into heat by resistance overcome and by molecular activity excited in living tissue. Local and general diathermy are only manifestations, hence a definite quantity of heat may be developed in a part such as the prostate. The heating is vascular, nutritional and relaxing.

The source is a standard transformer delivering high potential current energized by a motor generator of not less than two kilowatts capacity. The portable apparatus sold in drug stores is useless because it deceives the public and the profession. The rheostat is the multiple sparkgap type and the switch has five stops. Each device regulates respectively the voltage and amperage. The meter reads 0 to 2500 and is of the hot wire type. The electrodes are of the high vacuum glass type for the Oudin current in rectal or urethral prostatic work; or the insulated tip rectal electrode with the large metal pad on the pubes if diathermic current be employed. The current (always continuous) should produce only a mild warmth. The milliamperemeter registers from 200 to 1000 milliamperes within tolerance. Treatments persist from ten to twenty minutes, on alternate days, and decongest the gland remarkably.

In modern urology diathermy is used to increase healthful hyperemia and nutrition whenever any other modality might be used. It therefore augments the action of any other modality if used first. General diathermy or autocondensation in prostatic lesions promotes absorption and elimination.

X RAY.

The x ray is stimulating or inhibiting according to dose. The stimulating dose causes hyperemia and cell action while the inhibiting dose produces tissue contraction and cell decline. These are the bases of action in prostatic cases. Hemorrhage may be controlled with the x ray. The source may be the static machine or the transformer. The static machine seems to have the advantage of about127,000 volts when the standard ball terminals (0.866 inch in diameter) are 15 cm. apart according to Harris and Reiss, both noted and independent investigators. Such voltage gives greater penetration than that from a transformer having greater amperage but lower voltage. X ray treatment with the static machine for thirty minutes at 2 to 2.5 milliamperes thus delivering seventy or seventy-five milliampere minutes may be more serviceable than treatment by a transformer delivering 10 milliamperes for two to two and a half minutes, in total 20 to 25 milliampere minutes under considerably lower voltage and lower penetration but higher burning powers. This comparison is probable but is still under study. The x ray tube vacuum should back up a five inch spark gap between the ball terminals. This gap is equal to a ten inch distance between the pointed terminals of the transformer machines. A transformer with standard ball terminals will deliver about the same voltage but the higher amperage is almost sure to burn the patient. Burns with the static machine are rare, when compared with remarkable results.

CONCLUSIONS.

Electrotherapy is by no means a cureall in urology. Improved appliances, better diagnosis, finer selections of cases, lead to better recognition of its value.

Like all other measures its results are not constant in that sometimes it fails where success is expected and succeeds where this outcome is not looked for. A modality will benefit a given lesion in several patients and give little result in another group having apparently the same lesion. These patients in turn will accept a modality not usually employed for the same purpose.

After about eight years of careful study and work I am of the opinion that electrotherapeutics has a definite application in urology. It is by no means consistently positive and has its contradictory failures exactly as all other methods of treatment have had, do have and will have. It possesses one unquestionable advantage, which is that it does not add to the destructive process of the disease unless inexcusable blunders are made. Further without doubt it creates a healthy circulatory condition deep in the affected part, probably both through a local tissue and peripheral nervous influence. Unlike the average local application it does not cause exfoliation of epithelium and thus add to a process already existing as in gonococcal infection.

In acute infections when the mucosa is so irritable that no instrument may be inserted only the external forms as in x ray and radiant light and diathermy are possible.

In subacute conditions especially when instillations are employed in common practice the negative pole of the static machine and the high frequency current of mildest possible strength are of great value. Always the glass tube electrode with the vacuum exhausted to the first x ray degree must be applied otherwise disappointing results will ensue. These details work out remarkably in curing the damaged mucosa after severe mercurochrome and acriflavine applications.

Where massage influence is called for the positive pole of the static machine is in order or the mild sinusoidal current combining faradism and galvanism.

Where dilatation is required, as in stenosis of the uterine os or in urethral stricture, the negative galvanic pole is very valuable. When stimulation and mild caustic action are sought for, then the galvanic positive pole is used cautiously.

For penetration of various medicaments—notably copper, zinc and iodine—ionization is the method. The copper and zinc must be attached to the positive pole and iodine to the negative pole. Too much caution can not be used with ionization until real skill is established.

Electrotherapy cannot be learned in a short time but it will reward all the time and energy employed both in learning and in applying it. With the caution and limitations indicated herein I recommend it highly.

Physiotherapy in Orthopedics*

By CHARLES R. BROOKE, M.D.,
New York,

Passed Assistant Surgeon (R), U. S. Public Health Service; Chief, Physiotherapy Clinic, U. S. Veterans' Bureau, New York City.

Physiotherapy in orthopedics has been used successfully and extensively during and after the world war in military hospitals and government institutions. The following information is based on an experience of six years in military orthopedic work with a close follow up of patients receiving physiotherapy. This work started in the British war and base hospitals and was followed continuously in U. S. Army hospitals, U. S. Public Health Service hospitals and finally in the U. S. Veterans' hospitals and clinics. The past two years have been wholly devoted to general physiotherapy. I am convinced that modern scientific physical modalities, properly combined with orthopedic surgery and prosthesis, is now an important part of the orthopedist's armamentarium.

The large number of orthopedic disabilities resulting from gunshot wounds and other injuries among service and exservice men presented difficult tasks to solve. It was largely through the medium of physiotherapeutic modalities that these complicated disabilities and marked deformities were successfully treated and maximum improvement given. It certainly can be said that physiotherapy in conjunction with modern medicine and surgery has been a big factor in rehabilitating our maimed exservice men so they could become useful citizens, successful in various callings. Since space does not permit of individual case reports with progress notes and results, consideration will be given here to the *modus operandi* of the different physical modalities, the technics used, the action and reactions on tissues and the kinds of cases successfully treated.

We have at our disposal such physiotherapeutic means as massotherapy, thermotherapy, hydrotherapy, radiotherapy, actinotherapy, electrotherapy and mechanotherapy.

In the application of these classes of remedies, it is well to consider the various types of inflammatory reactions. Inflammation, as we all know, is nature's effort at preventing and repairing damage done or in the process of being done by an irritant in the living tissues of the body. There are three stages of inflammation, adequate, inadequate, and excessive. When the reaction is an adequate inflammation, recovery occurs by resolution. An inadequate inflammation is a progressive acute, subacute and ultimately a chronic inflammatory process or disease condition. An excessive inflammatory reaction is an acute form of inadequate inflammatory reaction occurring less frequently and producing stasis, necrosis and granulation tissue. The application of physical therapeusis to the body is effective only as it controls inflammatory reactions. It is of the utmost importance to make an accurate diagnosis of an existing condition, for this purpose utilizing x ray and laboratory findings, together with all necessary clinical evidence pertaining to the case before instituting physiotherapy. Several different physical treatments should be properly combined in sequence to produce a cumulative effect; single treatments prescribed at infrequent intervals are only mentioned to be condemned.

The oldest, most widely known and used modalities are, massage and radiant light and heat, wrongly known as baking, the latter term almost entirely discarded in recent years as being inappropriate and misleading. Manual massage with its sequence of movements includes active, passive, assistive and resistance exercises, special manipulations, remedial and corrective gymnastics. Following orthopedic operations, major and minor in character, the value of radiant light and heat and massage can not be overestimated. It can be applied in conjunction with the wearing of splints and bivalved casts, that can be removed for treatment and reapplied immediately following application. Radiant light and heat implies use of different styles and sizes of radiovitant applicators and deep therapy lamps. These applicators are equipped with four or more carbon or Mazda bulbs of 60 to 150 watts each, depending upon the part treated and the action desired. This form of convective heat produces a superficial hyperemia, thoroughly warms the superficial tissues and relaxes tense musculature, preparatory to massage and other treatments. It has marked derivative effects for relief of pain and irritation in neuritis, myositis and fibrositis, that often accompany conditions of an orthopedic nature.

---

*Published by permission of the Surgeon General's Office, U. S. Public Health Service.

Where there is pain, congestion and swelling after operations, the deep therapy lamp with its 1500 watt cobalt blue bulb filtering out many of the long heat rays has a decided sedative effect on the tissues, producing a deep, effective hyperemia to relieve the localized congestion. It also relieves pain by lessening nervous sensibility and regulating functional activity of the tissues. Heat produces a reflex effect upon blood supply, now well understood, various superficial and cutaneous areas reflexly related to deep internal organs being favorably influenced accordingly. Where there is superficial infection, unhealthy and unhealed scars, with draining sinuses in situ, the actinic rays are used, following deep therapy radiation, for bactericidal and healing action. The action of actinic irradiations has been found to be greatly and remarkably beneficial in active tuberculosis of bones and joints. Massage and exercises should follow radiant light and heat and deep therapy applications, to reduce swelling and congestion by stimulating circulation and absorption, and relaxing contracted and spastic musculature. The applying of suitable supports is necessary after treatment for some of these patients. Fractures should receive treatment as early as possible by radiant light and heat or hot whirlpool baths followed by light massage of the part. Muscles above and below the site of fracture are then to be treated, but no movements or exercises allowed for the first days. The employment of movements and exercises is to be guided entirely by x ray findings and the progress of the case, but should be started sufficiently early to obtain complete function in the minimum of time.

In case of flail joint, where operative procedures are contraindicated and after repeated attempts by surgical repair fail to be successful, the use of massotherapy with selective exercises and movements persistently and judiciously applied to muscles acting on the joints steadily increases function in the extremities. The development of muscle power and gradual increased range of motion in such a case, surprising to say, often gives an extremely useful extremity. The use of simple mechanotherapy also aids in muscular reeducation and in function of disabled joints.

Corrective exercises and remedial gymnastics are valuable adjuncts in treatment of functional scoliosis, lordosis and static strains of the back with postural defects.

Mechanotherapy is a valuable physical means for muscular reeducation, development of power, coordination and mobility of joints, following injuries and gunshot wounds with impaired function of muscles and joints.

Massage of amputation stumps should be started as soon as scars are healed, but should always be preceded by radiant light and heat or hot whirlpool baths. The massage at first must be light, increasing as the tolerance of the tissues permit. Exercises are valuable, active and passive movements being absolutely necessary to prevent deformity with limitation of motion and atrophy of tissues from disuse. As much pressure and force as is bearable should be made to end of stump to lessen liability of exostosis formation. These factors are all important to render the stump suitable for weight bearing when an artificial limb is supplied.

Mechanical vibration is a useful modality. It gives a regular stroke with deep massage and percussion effect and is more efficient than the manual massage in certain body regions. Vibration to the spine is particularly effective in many forms of backache, lumbago, sacroiliac and lumbosacral strains, with chronic myositis and neuritis. These conditions should first be treated with diathermy or the deep therapy lamp before vibration is applied.

It is important to give each treatment for a sufficient length of time to produce good results, and for this reason (of course, with certain exceptions), the average treatment period is twenty minutes. This is really a short intensive application, but longer treatments are sometimes necessary to produce the effects and reactions desired. Treatments of short durations are to be condemned as needlessly prolonged and unsatisfactory in the end.

Local hydrotherapy is administered by submersion of the extremities in the latest designed arm and leg whirlpool baths, these being equipped with the adjustable ejector and aerater. The nature of the cases benefited by this form of treatment are gunshot wounds of the extremities, recent fractures, joint injuries, painful amputation stumps with swelling and edema, adherent, painful scars, nerve injuries with peripheral paralysis and neuritis. The importance of the whirlpool bath in these conditions cannot be overestimated for the following reasons: It gives a gentle, soft, soothing massage to the affected areas; relaxes muscle spasm; reduces edema and also effusion of joints; relieves the pain about adherent scar tissues; produces a sedative effect to nerves and increases local circulation, thus relieving cold, sweaty, cyanosed conditions of extremities. This treatment has been found to be of great benefit in pes planus and allied disabilities of the feet, as a preliminary treatment before receiving massage, forcible exercises and manipulations. It also increases the conductivity of the tissues to electrical currents; this, in my experience, materially hastens muscular response to galvanism and sinusoidalism in old peripheral nerve lesions with partial or complete paralysis.

HIGH FREQUENCY CURRENTS

Entering upon high frequency phenomena it is well to understand the oscillatory character of the condenser discharge. This is brought about by the sudden disruptive discharge causing a breaking down of the cohesion between the particles that are expelled in a diffuse oscillatory manner across the spark gap, which controls the current flow.

Diathermy (thermopenetration), a direct form of high frequency current of high amperage and relatively low voltage, is obtained from the d'Arsonval or bipolar current of a high frequency machine. This form of deep heat penetration can be given in two ways, sedative and stimulative. Experience has shown that it is the treatment *par excellence* in bone and joint diseases and injuries.

Sedative diathermy, the type usually indicated, is where a long continuous steady heat is driven through an affected part usually to the tolerance of the patient. The amount of heat varies with the resistance, time of application, part treated and size of electrodes, bone structure giving the greatest resistance. The current is stepped up from and down to zero gradually, allowing five minutes to reach the maximum and five minutes to be reduced to zero. The average duration of treatments should be about twenty minutes, in some cases longer, but almost never shorter.

Stimulative diathermy is much less frequently used, chiefly indicated and used successfully in promoting callus formation in sluggish healing fractures and in gunshot wounds where there is loss of bone substance. In this form of treatment the current is stepped up rapidly and reduced abruptly by closing the spark gap suddenly. The object being to stimulate and irritate the bone substance by short intensive flow of current to produce osteogenesis. The treatment should require only one third the time and about one third the dose of a sedative treatment.

The effects of diathermy vary as to the time of the application for an effective dose. It varies directly as the square of amperage; for example, by raising the amperage from 250 milliamperes to 750 milliamperes, which is three times the amperage, but is nine times as much heat produced in the tissues. It varies as to the resistance of the part treated; the more dense the tissue, the greater the resistance. The smaller electrode surface is active; the larger electrode surface is inactive. This is brought about by the current being concentrated from the large electrode on to the small electrode with great heat formation and the current from the small electrode is diffused onto the large electrode with less heat formation. In electrodes of the same size the maximum degree of heat is half way between electrode surfaces. The skin is little affected by the passage of the current in diathermy, the heat concentrating in the bone and deeper soft tissues. Do not use more than 1000 milliamperes to each sixteen square inches of electrode surface. The tension for therapy ranges above 10,000 volts with a frequency of above 200,000 oscillations a second: The frequency must always be over 10,000 a second to be safe: an alternative current under this figure will cause tetanic contractions of the tissues. The electrode material is a composition lead and block tin, 50 per cent. each, 22 gauge, known as Crooke's metal; it is easily cut and shaped for areas to be treated. The best clips used to connect rheophores to the d'Arsonval binding posts are of the Fahnestock type, any style being used. The electrodes are applied by either the cuff or plate method, the size and shape depending on the part to be treated and the nature of the existing pathology. Soaping of electrodes for treatment and similar preparation of the skin over the part to be treated should always be carefully done to insure accurate contact. This makes the difference between a pleasant, efficient treatment and a burning, stingy and occasionally shocking, ineffective application. The electrodes, selected for the part to be treated, are placed in warm water for a minute or two, during which time the skin over the area to be treated is thoroughly moistened with soap and water. The surface of the warm electrodes to be applied to the skin is now thoroughly moistened with soap and water and applied over the prepared area of skin. Always be sure that the electrodes are in perfect contact with the skin and fit in perfect coaptation over bony prominences. This is necessary to prevent the jumping or arcing of the current from the edges of the electrode to skin, as this would produce a disagreeable, prickly, burning sensation with subsequent development of a burn.

In treating joints of the hands and feet diathermy should be given by placing the hand or foot in a small amount of salt water in a suitable white enamel basin. This method has proved to be more efficient than by applying the electrodes to the smaller joints where only a minimal amount of current could be given; even then there is great likelihood of the current arcing and producing a burn. When treatments are given to the arms and the legs in salt water, one electrode is placed in the water and attached to the rheophore: the other electrode, in form of a cuff, is placed above and around the wrist or the ankle joints, connections to the machine being made as usual. This form of application permits of sufficient milliamperage to obtain effectual results and further use permits of concentration of current to particular affected digits by raising other digits out of the water leaving the affected one to receive all the current. When all digits are affected, alternate the concentration of current by lifting first one and then the other out of the water. A small amount of water to cover fingers or toes is all that is necessary, too much water making the resistance too high.

Among the important actions of sedative diathermy on tissues are: produces heat in accordance with the resistance of the part; increases the local blood supply; dilates the arterioles and produces hyperemia of deep tissues and bone substance; disintegrates organized or partially organized articular and periarticular exudates; dissolves excessive, painful callus formation and breaks up fibrous ankylosis and adhesions; it is a decided sedative, relieving acute pain in myositis and neuritis; finally, it relaxes tense and spastic musculature.

The nature of lesions materially benefited by diathermy includes all types of gunshot wounds with fractures followed by subsequent deformities of bone and joints: panfibrous and hemifibrous ankylosis of joints with articular and periarticular adhesions and exudates after long immobilization in splints and plaster casts; acute and subacute articular rheumatism and all arthritic conditions with deformity and limited range of motion; acute sprains and strains of joints; hypertrophic and rheumatoid arthritis (these being benefited partially, depending on duration and extent); traumatic myositis and neuritis accompanying joint and bone injuries; bone infections, chronic osteomyelitis, osteitis and periosteitis.

Diathermy has a markedly relaxing effect on ligaments, muscles, and joints, thus preparing them for massage, active and passive exercise with forcible bending, stretching and special manipulations. It is indicated in joint pathology with diminished range of motion. Sacroiliac injury, with slipping of the joint and consequent strain, is successfully relaxed and the joint manipulated back into position.

The crossfire method of diathermizing joints is used by me with notable success. It is a method of particular value in knee joint disabilities. The technic of this method is carried out by the sequence of four different applications of electrodes as follows: The first treatment is given by the cuff method, cuff electrodes being placed around the leg just below the patella ligament and around the thigh just above knee joint articulation. The second is carried out by placing plate electrodes above and below the knee diagonally opposite each other. The third treatment is given by reversing the electrodes and in the fourth and last application, the electrodes are placed one over knee cap and the other in the popliteal space. The duration of each application and treatment is twenty minutes; this is repeated as often as indicated, but alternate days should suffice in the average case. The seance is repeated until maximum benefit has been attained. This thorough diathermizing of a joint gives satisfactory results where there is a diffuse articular and periarticular arthritis and fibrosis with effusion and pain. It must always be remembered, in the application of electrodes, that the smaller active electrode is placed over the site of greatest disability with the larger inactive electrode diametrically opposite. This plan brings the involved area between them with edges far enough apart to prevent arcing of current from the electrodes. Diathermy of areas should always be followed by either massage and exercises, sinusoidal wave, rhythmic faradic or static wave or sparks and brush discharge. This combination with any of the above modalities hastens absorption, decongests the tissues, relieves pain and gradually restores the tissue to normal consistence, hastening the return of normal function. Diathermy is contraindicated where there is walled in pus, likelihood of hemorrhage, active tuberculosis of bones and joints and in malignancy.

The unipolar or Tesla current from the high frequency apparatus is used occasionally in cases of an orthopedic nature in conjunction with other modalities. It is a current of high voltage and relatively low amperage, being given in two forms, sedative and stimulative, with vacuum and nonvacuum electrodes. The nonvacuum is preferred and is four times more efficient. The sedative form is given with a mild current with the electrode touching and moved slowly over the surface treated. The stimulative form is given with more current and with the electrode raised one to three inches above the surface treated, producing a sparking effect, the intensity of which varies with the condition. The combined sedative and stimulative treatment is particularly useful in phlebitis, venous stasis, varicose veins and ulcers and in trophic abnormalities of the extremities. The sedative form, as the name implies, relieves pain and produces superficial hyperemia. The stimulating form decongests and relaxes superficial tissues and increases circulation by its sparking effect.

Static electricity or the frictional current is of extremely high voltage and extremely low amperage. The three modalities extensively used in this form of treatment are the static wave, sparks, direct and indirect, and static brush discharge. Static electricity is essentially mechanical inaction, but also has some electronic action in the tissues. The principal indication of this type of current is to relieve pain by decongestion of tissues produced by an even molecular electronic massage. The socalled hookups for the different modalities of the machine vary according to different authorities. I use the following technic and have found results satisfactory: the patient is seated on an insulated platform, the negative pole of the machine being grounded, and, if using the wave treatment, is connected to the positive pole. For both the static sparks and the brush discharge, the patient is connected to the negative pole of the machine, the positive poles being grounded: the spark ball or brush instrument and the operator are grounded, and I advise attachment of the Leyden jars in the wave treatment and also when the sparks are not sufficiently strong.

In cases with localized pain and swelling, the wave treatment is especially indicated, but the area should be diathermized beforehand to soften any organized or partially organized exudate or congestion. Method of application: An electrode of 22 gauge Crooke's metal, cut exactly to fit the area, is bandaged on and connected with positive terminal of machine. The contractions should be limited to three or four a second, to permit of full relaxation between each contraction of the tissues. When the area of pain and congestion is more diffuse as, for instance, a sciatic neuritis affecting the entire course of the sciatic nerve, the sparks are given up and down the nerve course, light at first and gradually increasing to tolerance. This is followed by the static brush discharge (pencil effleuve) that has a sedative and decongestion effect. In sciatic neuritis the wave should be given first over the sacrosciatic notch and then followed by the sparks and pencil effleuve as stated. above. The time of treatment should be from ten to thirty minutes, depending on the condition of the part treated. This permits ten minutes for each modality in sequence, wave, spark and brush discharge, the preferable technic. Longer duration of treatment is necessary when only a single modality is given. The nature of cases responding to these modalities are acute sprains and strains of all joints, joint effusion, synovitis, bursitis, sciatica neuritis, chronic myositis and neuritis of all types. Treatment should always be preceded by some form of heat, preferably diathermy or deep therapy.

My desire in this article is not to hail physiotherapy as a panacea but to emphasize the efficacy and potency of physical forms of effective therapeutics, scientifically applied in orthopedic conditions.

Physiotherapy in the Medical Department of the United States Navy

By ERIK G. HAKANSSON, M.D.,
Washington, D. C.

In the naval medical service, physiotherapy now includes massage, medical gymnastics, hydrotherapy, radiant heat and light therapy, actinic ray therapy and electrotherapy.

In the term medical gymnastics are included all the methods of systematic exercises of the motor apparatus for therapeutic purposes. Both the manual and the mechanical methods are used. Games and sport and occupational therapy are also utilized. In hydrotherapy, applications of practical nature and known effect are used, such as the ablution, the sheet-bath and the cold friction bath, the cold pack and the continuous bath, the circular douche, the jet and fan douche, whirlpool baths and fomentations. Radiant heat and light are applied by means of different types of incandescent lamps and by electric light bath cabinets. For actinic ray therapy, the mercury vapor quartz lamps and other arc lamps are utilized. Direct sunlight is also used. In electrotherapy use is made of the galvanic, faradic and sinusoidal currents and the various modalities of the high frequency current and static electricity.

In the latter part of 1919 a separate department for physiotherapy was established at the Naval Hospital, Brooklyn. A complete equipment was acquired. Navy nurses and hospital corpsmen were trained as operators and a high standard of skill was soon attained. The hospital staff found physiotherapy a valuable aid in the treatment of a great variety of injuries and diseases and utilized it to its full capacity. During the three years and a half that it now has been working the change from wartime to peace time conditions has occurred and an entirely new set of officers and nurses has succeeded the staff under which the physiotherapy department evolved. It is significant to note that the department still has practically the same extent of usefulness. This bears out the assumption heard from various sources nowadays that the utility of physiotherapy is not restricted to the functional restoration of maimed victims of war injuries, but that it should be regarded as a fundamental branch of medical and surgical treatment in time of peace as well.

The Bureau of Medicine and Surgery is now realizing a plan to place physiotherapy at the command of all naval hospitals. Three naval hospitals, besides the Naval Hospital, Brooklyn, have now physiotherapy departments in commission and within the next six months five additional hospitals will be equipped and provided with trained personnel for this method of treatment.

The Navy does not employ reconstruction aides as operators in physiotherapy, but trains its own personnel, nurses and hospital corpsmen, for this purpose. This training is carried out at the Naval Hospital, Washington, D. C., where a physiotherapy department, with special advantages for training of personnel has been organized. The minimum time for the course of instruction is four months. The aim of this training of the nurses is to make them skillful technicians capable of intelligent application of physiotherapeutic measures, at the direction of medical officers. The hospital corpsmen are expected to meet these requirements only in hydrotherapy. Their training in the other methods of physiotherapy is considered satisfactory when they can work as reliable assistants to the nurses.

Physiotherapy has also been placed on the curriculum of the Naval Medical School. The course includes eight lectures with clinical demonstrations and eight hours of practical work. The training of the personnel and the instruction at the Naval Medical School are in charge of medical officers who have had special experience in physiotherapy, and who have been afforded ample opportunities for study.

Through this system of instruction, the peace time Navy will soon have most of its medical officers familiar with the principles and indications of physiotherapy and a number of medical officers will have special knowledge of the subject and considerable experience in the training of operators. Furthermore, there will be many nurses particularly skilled in the application of the various modalities of physiotherapy, and a considerable number of hospital corpsmen sufficiently trained to work satisfactorily under supervision. It is obvious that these conditions will permit of a quick and easily accomplished expansion in case of a war emergency. By merely placing the above mentioned medical officers in charge of the various physiotherapy departments, each naval hospital can be made a training unit capable of supplying its own needs in physiotherapy personnel. With trained personnel available, the problem of expansion is practically solved. Other necessities, such as additional space and more equipment would be less urgent, since, undoubtedly, the skillful human hand working intelligently is the most important instrument.

The Employment of Some Forms of Electricity in Cardiovascular Diseases

By EDWARD C. TITUS, M.D.,
New York.

Realizing that in the treatment of cardiovascular conditions electrotherapy constitutes only one of the many remedial agents, I shall limit myself in this brief paper to a discussion of the uses and indications of the different electrical modalities. I have therefore omitted any reference to the other important elements to the treatment, such as diet, exercise, general hygiene, hydrotherapy, and the administration of the various medicinal remedies.

Circulatory disorders, as commonly encountered, may be divided into local arterial spasm, general hypertension, low arterial tension, abnormal relaxation of peripheral bloodvessels, and changes in cardiac rhythm. These may occur in the course of valvular lesions, hypertrophy or dilatation of the heart, or of cardiorenal disease. I shall describe briefly the action of the various currents and indicate the conditions in which they are chiefly applicable.

HIGH FREQUENCY CURRENTS.

The commonly termed high frequency electrical current and its two important subdivisions, local and general diathermy, may be briefly defined as very rapidly oscillating currents which are converted into heat by the resistance they encounter and the molecular motion set up in the living tissues. The newer type of high frequency electrical apparatus enables us to introduce heat even into the deepest structures, and this too in a definite dose. When diathermy is applied in sufficient quantity to the heart and greater bloodvessels in cases of hypertension, the first effect observed seems to be upon the vasomotor nerves, evidenced by relief of vascular spasm and an equalization of the circulation, with increased elimination of toxic gases and solids from the fluids of the body. This is shown by the emanations from the skin and mucous membranes and by the increase of toxic products found in the urine after each treatment. One can readily appreciate the advantages of this procedure even in cases where extensive changes have occurred in the bloodvessels.

From a report on high frequency currents read by de Kraft before the American Electrotherapeutic Association (1) we quote: "High frequency currents enable us to raise the blood pressure when too low, as well as to lower it when too high. We know that there exist both vasoconstrictor and vasodilator nerves. It appears certain that as the result of a variety of toxic products generated in the human body, we may have either an irritation of the vasoconstrictor or of the vasodilator nerve.

"The first effect of the great rapidity of the succeeding groups of oscillations is an intense heating of the surface of the body and of the blood. This, in turn, stimulates the great system of vasomotor nerves, resulting in peripheral dilatation of the bloodvessels, and, at the same time, in stimulation of the sweat glands. It would appear that the sympathetic nervous system is stimulated in a most profound manner."

The effect of high frequency currents on the sympathetic nervous system is well illustrated by observations made by Sherbak (2). He employed diathermy by means of two electrodes with a combined area of 57.5 square cm. The upper electrode was applied to the upper cervical vertebræ and the lower to the middle dorsal. From five hundred to seven hundred milliamperes were passed for five or six minutes. In a case of severe headache which accompanied right sided hemiparesis, hemianopsia with atrophic changes in the eye grounds and loss of hearing, twelve to fifteen applications relieved the headache. In another case of cerebral syphilis ten applications relieved the headache, hyperemia and the noises in the ears, and restored the patient to working capacity. It is interesting to note that the Argyll Robertson sign, which was present, disappeared after the treatment.

Equally good results were obtained in fifteen cases of functional disorders accompanied by circulatory disturbances in the head. In the majority of cases, the blood pressure, when above normal, was lowered after each treatment, and remained so after a number of applications. This author cautions against prolonged treatment in view of the marked circulatory changes produced in the cerebral circulation, which, he maintains, may cause anemia of the brain, low blood pressure and excitement. In my experience these symptoms do not occur if the diathermy is applied directly through the brain. The value of diathermy in arteriosclerosis of the brain is remarkable and permanent benefit has been noted.

Numerous observations enable us to assert that a normal blood pressure in an otherwise healthy person is never influenced by high frequency currents if employed in moderate doses.

GALVANIC CURRENT.

This is a continuous flow of energy producing polarity effects by which it causes electrolytic or chemical changes. The latter changes may be nutritional or even destructive, depending upon the method and degree of application. The passing of the continuous current of five to ten ma. through the brain for prolonged periods at each treatment has been followed by marked nutritional improvement in both the objective and subjective symptoms which so commonly follow profound cerebral changes, and when this modality is preceded by local diathermy for twenty minutes the effects seem to be greatly intensified. Because of the pronounced beneficial nutritional changes induced by this combination of electrical forces, their employment in hypofunction of the liver, kidneys and the endocrine system will be found most helpful. The prolonged use of mild galvanism for one half to one hour, supplemented by diathermy, is the approved treatment for inducing absorption of retinal hemorrhage, as well as the cerebral changes associated with the slow and often incomplete recovery from apoplexy.

FARADIC CURRENT.

The Bergonié method of treating obesity is the application of the induced current from a high tension faradic coil with comparatively slow vibrations which are tuned to the rate of muscle fibrillation of thirty a second, and administered in surges at a frequency to correspond with the heart impulses. In some patients with rapid heart action the contractions are slowed to every second heart beat. This procedure is a particularly serviceable and safe means of treating muscular weakness associated with obesity and cardiovascular changes. For further information concerning this method I would refer you to a recent article of mine which embodied my experience in the treatment of obesity (3).

THE SINUSOIDAL OR RHYTHMIC WAVE CURRENT.

This is a slowly swelling, unidirectional, continuous electrical discharge, which reverses its polarity at the completion of each cycle. It produces alternate contraction and relaxation of both striped and unstriped muscular fibres, and when these effects are regulated to correspond with the frequency of heart action, the nutritional changes in the muscular system are greatly influenced. In gastrointestinal dysfunction, associated with cardiovascular disorders, this dependable current will help to correct some of these disturbances through the removal of effete material, and the improvement in the intraabdominal pressure resulting from the increased tone produced in the abdominal viscera and muscles of the trunk.

STATIC WAVE CURRENT.

This current is a pulsatory high voltage electrical discharge with an initial low amperage. It can also be defined as a capacity discharge obtained from a unidirectional source of energy. Because of its high voltage, low amperage, and the wide dispersal of its pulsatory discharge throughout the body, the static wave current enables us to produce rapid electrical and mechanical variations in the human system. Both physicists and physiologists have determined that this current induces tissue contractions in all structures which are capable of contracting, and even in the protoplasm of the cell. In conditions of hypotension, with or without engorgement of liver, spleen or kidney, the static wave current will effect a more normal distribution of the blood by the vibratory effect set up in the cells of the body and the removal of venous stasis of the liver, spleen and kidneys.

In conditions of low blood pressure, we can raise the tension by stimulating the end organs of the sensory nerves by means of the wave current or the resonator effleuve, preferably from a static machine, or by rapidly rubbing a glass vacuum electrode attached to the Oudin resonator over the surface of the body. Whatever static method we employ to achieve our object, we notice, almost invariably, that as the circulatory disorder improves the mind clears, ideas flow more freely, and there is an increase of bodily vigor.

RÖNTGEN RAY THERAPY.

Röntgen ray therapy can be both stimulating and inhibitory in its effects, depending upon the degree of application. In small doses, which are usually followed by a reactionary hyperemia, it increases cell activity. By large doses we induce tissue contraction and inhibit cell growth through arresting the functions of the enzymes in the structures acted upon. This agent is now a recognized method of treatment in cases of uterine fibroids and enlarged prostates associated with and often a cause of, cardiovascular diseases. It may also be employed in checking the excessive activity of the adrenals.

PHOTOTHERAPY.

The general application of phototherapy consists practically in the use of the electric light bath, and since much of the benefit to be derived from this agent will depend upon the apparatus employed, I will first give a description of what has proved to me to be the most satisfactory type of cabinet.

An electric light cabinet should be constructed according to the following plan: It should be octagonal in shape, four feet square by five feet high; the lining should be of white blotter and not mirror surface; the source of light should come from one hundred forty watt tungsten lamps, conveniently arranged, so that they will be under control from within by properly placed switches, one half or the full number of the lights to be employed, as desired. The cabinet should be partly open at the top, and it should have an air vent three inches in diameter in the centre of the floor, over which is placed a low stool eighteen inches high upon which the subject is seated. (It has been found that a ventilated room is much more quickly and evenly heated artificially than one that is closed or sealed.) The further advantages of this construction, compared with the older form of closed cabinet, are that a large volume of light with a minimum amount of heat is produced in the cabinet, that the emanation of noxious gases and odors from the human body are quickly carried off, that the degree of cutaneous hyperemia and diaphoresis is much more intense, and that the usual depression and other unpleasant symptoms are entirely obviated. The chief condition in which the electric light bath has proved to be most serviceable is arteriosclerosis. In the majority of cases of arteriosclerosis in the earlier stages I have advised the regular use of these baths, with beneficial results, and I firmly believe that they have warded off the more serious organic changes which otherwise frequently ensue. The effects of the bath are:

1. To induce intense hyperemia or reddening of the skin and thus reduce the congestion of the deeper organs, which is frequently present.

2. To increase elimination by way of the lungs and skin. It has been found that during and following the bath the elimination of carbon dioxide is practically doubled, while the profuse perspiration produced carries away much toxic or poisonous material, and in that way relieves the overtaxed kidneys. As it is generally accepted that toxemia plays an important part in the causation of hardening of the arteries, the benefit to be derived from this method is readily apparent.

In conclusion, I would say that the value of electricity in the treatment of disease depends upon the judicious selection of the modalities which clinical experience has shown to be indicated in the individual case, as well as upon the proper method of employment. As pointed out, it is often necessary to combine several electrical modalities in order to obtain the desired result, and this can only be determined by a thorough knowledge of the conditions present. There is no reason why the general principles governing the use of electricity in the treatment of disease should differ in any respect from those applicable to the administration of various medicinal remedies, in regard to both physiological action and indications. Moreover, the study of the action of the various electrical currents upon the human body in health and disease is greatly simplified by the fact that we are not called upon to consider the occurrence of toxic effects and idiosyncrasies which occupy so important a place in pharmacological investigations.

Exercise in Therapeutics

By HARRY EATON STEWART, M.D.,
New Haven, Conn.

There are certain fundamental factors upon which the body is absolutely dependent for its ability to function normally. Among these are rest, food and exercise. In the mode of living into which we have been forced by modern civilization none of these essential factors has been so completely modified as that of exercise. Not only both men and women, but most children have but a fraction of the exercise which their forefathers were compelled to take.

In the absence of organic disease there is direct relationship between the condition of the skeletal muscles and the tone and efficiency of the heart and nonstriated musculature of the gastrointestinal and vascular systems. Proper exercise of the larger muscle groups influences directly the adequacy of respiration, the cerebral and systemic circulation, intestinal elimination and the ability to maintain that good posture which aids the body in functioning efficiently as a machine. The direct relationship between exercise and muscular power, the mobilization of joints, and relief of lymphatic and venous stasis is clearly apparent.

Quite recently G. O. Broun, of the Rockefeller Institute, has demonstrated that exercise stimulates the hematopoietic system to greater activity as shown by the increased number of reticulated erythrocytes after exercise in animals unused to it. In his investigation muscular training seemed to increase greatly this function of the bone marrow.

A broad view of any phase of therapy must include the prevention as well as the treatment side of the story. It was but a comparatively short time ago that therapeutic exercise, especially when accompanied by massage, was regarded as an almost complete field of physical therapeutics. The Swedes particularly have developed this type of treatment. In the hands of a well rounded physiotherapist today scarcely a condition would be treated by these means alone. Other forms of physical therapy, such as radiant light and heat, ultraviolet light and the various modalities of electricity, would be blended with these measures in obtaining the quickest results.

Exercise was one of the first physiotherapeutic measures to arrest the interest of medical men in large numbers, which accounts for its common recognition by the profession today. William G. Anderson, of Yale; D. A. Sargent, of Harvard; R. Tait McKenzie, of Pennsylvania; Jesse F. Williams, of Columbia; C. Ward Crampton, of New York, and many other medical men working in the field of physical education, have done valuable work in the subject of therapeutic exercise. Their researches however, have not been published in medical literature and for this reason a brief review of some of the principles and methods involved in exercise therapy are here presented.

Prevention includes adequate physical training for the young and the employment of sports and games suitable to various ages throughout life. The youth of both sexes must be adequately prepared to stand the severe drains on their physical reserve which the complexities of modern life have made it impossible to avoid. Postural defects of head, shoulders, spine and feet by increasing mechanical difficulties of standing and of motor activity may lead to organic lesions if uncorrected. These conditions will be considered along with curative measures in this paper. On the strictly therapeutic side we have both medical and orthopedic gymnastics. Medical gymnastics are used in the functional cardiac conditions, visceroptosis and intestinal stasis.

Tachycardia and irregularities of the heart beat not associated with organic lesions in the bundle of His were frequent in our army service work. A valuable paper on these conditions was written by my successor in the Bureau of the United States Public Health Service, Major Burt W. Carr (1).

In both of Dr. Carr's cases at Walter Reed Hospital and in the group at Cape May and other army hospitals, the old Schott-Nauheim resistive exercises were replaced by a carefully graded, slow, rhythmic type associated with the respiratory movements. The men were graded according to their initial pulse rate and cardiovascular adjustment into three groups, the first of which were given light passive or active movements, in a recumbent or reclining position. The commands were given slowly in a monotonous tone of voice and all effort was made to keep the environment free from interference and excitement. The second group were given slow coordinated bilateral movements in a standing position which were gradually increased in number, speed and vigor of execution. The third group received snappy setting up exercises and games. Pulse records were kept and the men advanced as their condition permitted.

The work of Wilson, Halsey and Barringer, of New York, has caused us to revise somewhat our fear of exercise in organic heart lesions. They found only about two per cent. of the children so affected had a poor tolerance for exercise.

Visceroptosis and intestinal stasis are treated by lateral trunk and abdominal exercise consisting of trunk bending and twisting followed by bilateral bent knee, and straight leg raising, done lying supine or from hand suspension.

In most orthopedic conditions which we are called upon to treat by exercise there is a lack of power balance in two or more physiologically opposing groups of muscles. This inequality of strength is of course normally present in several parts of the body, the anterior tibial and calf muscle groups being one example, the upper back and pectorals another. When some condition arises, such as chronic fatigue, malnutrition, too rapid growth or accumulated toxins, which cut down muscular power generally, it greatly increases the relative advantage of the already stronger group. In such conditions we find the fatigue slump, muscle bound foot, and similar defects develop. In another case we have weakness due to overstrain associated with poor muscle tone, as in the flaccid flat foot. In still another group are to be found the peripheral motor neuron lesions including infantile and traumatic injuries.

In correcting these conditions we take advantage of the fact that as the muscle strengthens, the belly of the muscle becomes thicker and the points of origin and insertion brought closer together. To accomplish this result we exercise selectively the weakened and stretched group. The physiological opponents must at the same time be actively stretched, the tone of the entire muscular system brought up to maximum and occasionally, as in the common postural defects, the muscle sense must be reeducated. With these principles in mind it is in order to consider the number of conditions in which exercise plays a leading part in the treatment.

Head forward.—Vigorous retraction of the head first as an active exercise, later resistive, by the operator standing behind patient, and exerting counterpressure on the occiput, should be instituted. The chin is thrust forward and up and the head slowly and vigorously retracted with the chin lowered. If properly done the patient will feel the muscle contraction as far as the middorsal region.

Round shoulders.—Being practically always associated with a head forward position, the exercise described above should be given, together with the following special shoulder group.

For strengthening the upper back. 1. Raise arms forward, carry sideward and lower, keeping the shoulders well back. 2. Raise arms forward, bring the hands sharply to the chest, elbows back and lower, keeping shoulders retracted. 3. Raise arms forward and carry obliquely side upward and lower. 4. Rotate the arms slowly, palms outward, forcing the scapulæ closely together.

To stretch the pectorals. 1. Patient seated on chair, hands behind neck. Operator standing behind grasps upper arm and forcibly retracts shoulders. 2. Patient's back to the uprights between stall bars, grasps behind shoulders, keeping head, shoulders and lower back against the upright, executes a deep knee bending and straightening, retaining hand grasp.

To reeducate the muscle sense. Use full length mirror to correct posture and return several times during the exercise period, teaching the patient to assume and retain the proper attitude.

Scoliosis.—To stretch the contracted muscle on the concavity. 1. Lateral trunk bending toward the main convexity, hips fixed. 2. Hand grasp in front of shoulders on stall bars or horizontal bar, legs extended to the side of the main convexity. 3. Active spine stretching to fullest extent, walk on tiptoe.

To reeducate muscle sense. Use of the mirror in assuming full height and the correction of any unevenness in the shoulder level. To increase flexibility. 1. Trunk twisting from hand suspension. 2. Trunk twisting from standing position.

Lordosis.—To stretch out the contracted lumbar erector spinæ. 1. Long sitting. Sitting on a floor or table with legs extended.

To strengthen the weakened opposing group. 1. a. From supine lying, trunk raising to sitting position. b. Double knee raising. c. Double straight leg raising. 2. a. From hand suspension. b. Double knee raising. c. Double leg raising.

Weak feet.—1. Stand feet parallel and roll out. 2. Walk forward on the outer edge feet parallel. 3. Toe in and rise on toes. 4. Walk forward on the outer edge toeing in. 5. Ground gripper walk. (Attempting to dig the toes into the rug with each step).

Muscle bound feet.—1. Stand feet parallel arms length from wall, supported by straight arms, fingers pointing inward. Bend the elbows, lowering the body forward and keeping the heels on the floor. When this condition is associated with weak feet give the socalled weak feet group omitting the exercise rising on the toes.

Peripheral nerve injuries.—Perform a few entirely passive movements of each joint involved. As soon as the slightest active movement is possible, make them assistive in type—the patient doing all of the movement possible himself. With further recovery proceed to a few active motions so given as not to have the patient working against gravity. When possible advance to resistive movements against gravity, active opposition by the operator or apparatus to obtain this effect.

The early onset of fatigue always present in the subnormal muscles must be constantly held in mind and these exercises graded with extreme care as to type, number or repetitions and vigor of performance. In all postural defects faulty habits of sitting and standing must be corrected, the active cooperation of teacher and parent enlisted, the general nutrition built up and excessive burdens of mental or physical work or dissipation eliminated.

In closing, the point should be emphasized that all phases of physiotherapy which will aid in muscular nutrition or give sufficient contractile stimulation to prevent loss of tone, when active contraction is impossible, should be blended with the exercise régime. Only in this way can the best results be obtained in the shortest amount of time.

Exercise in the Treatment of Hypertension*

By C. WARD CRAMPTON, M.D.,
New York.

The use of exercise in the circulatory disorders is comparatively recent. The subject attracted my attention early in 1902, when I examined several thousand high school boys in connection with their physical exercise. Many were found circulatory invalids, and their cases were studied thoroughly with the purpose of making them as fit as possible under their handicaps, to engage in active, useful lives. Subsequently, as director of the department of physical training of the New York public schools, steps were taken to introduce physical exercise into classes organized for cardiac cases. This work has been developed by the Association of Cardiac Clinics.

There is an increasing confidence in the use of exercise in circulatory disorders, based upon the increasingly successful experience in its several fields. One of the most important of these fields is hypertension.

DEFINITION.

Hypertension is a symptom rather than a disease. It is apparently due to a hypertonic state of the blood vessels, particularly those of the smaller calibre, the arterioles and probably the capillaries.

It is evidenced by any elevation of the systolic or diastolic pressure, which is not due to physiological causes. A systolic pressure of over 140 mm. recumbent, or 135 mm. standing, and a diastolic pressure of 90 mm. recumbent or 95 mm. standing, requires explanation.

ETIOLOGY.

This state is a physiological reaction of the blood vessels to vasotonic influences which are usually toxic and act directly upon the arteries or indirectly through the nerves.

These vasotonic influences are in turn caused by 1. Infections. 2. Poisons from the intestinal tract and from outside the body. 3. Strains, acute or chronic. 4. Disharmonies, either metabolic or endocrine. There is usually a combination of these causes.

Hypertension usually has two stages; first, the functional stage where the symptom exists without discoverable structural lesions, and secondly, structural, where lesions are present. The functional and structural stages of these are sometimes called, respectively, the uncomplicated stage and the complicated stage. Lesions of the kind usually associated with hypertension, to wit: hardened arteries, contracted kidneys, and the like, may exist with no hypertension, and conversely, hypertension may exist without them.

TREATMENT.

The treatment of hypertension should be directed toward: a. The patient himself as a human being who has various physical and mental processes other than the hypertension. He has a life to live and he wants to be strong, happy and as useful as possible. b. The associated diseases of the arteries, kidney and heart, and nervous system. c. The sources of the symptoms and diseases (infections, poisons, strains and disharmonies). d. The hypertension, for it in itself may do harm; but no greater mistake can be made than to treat the hypertension alone.

ERRORS.

There are several common errors to be avoided, the most important of which is the tendency to treat the symptom, hypertension, and neglect the underlying physiological process. The next most common error is to recognize and treat these etiological processes, and to neglect the patient.

The most serious errors are made by those who rely upon one line of treatment for hypertension, regardless of the sources and nature of the condition. Within the last month I have seen a patient treated for high blood pressure in a hospital for two months by rest and restricted salt and fluid, while the antrum was full of caseous material; another, with the teeth all removed, low specific gravity, high blood nitrogen with static colon was kept in bed; another with a four plus Wassermann treated only by electricity and exercise. The instances of single track therapy may be multiplied.

Proper treatment of hypertension lies in planning a program of living, rather than in writing a prescription. Exercise, diet, bathing and recreation, regulation of work, entertainment, hydrotherapy, massage, electricity, and, if necessary, drugs, should be considered. The prescription must be for twenty-four hours, for seven days of the week, twelve months, and many years, rather than for a series of drugs, enemas, and baths. This involves a radical change of method from the ordinary textbook conception of hypertension to the conservative application of the newer phases of hygienic medicine, to living rather than to disease. Physicians are too frequently merely pathologists.

DIAGNOSIS.

There should be a thorough medical search through the whole patient to discover the causes of the symptom. One must not be satisfied to find one cause. All possible causes must be found or excluded. When a cause such as nephritis is found one must go further and discover the more remote source of the causes, and beyond them still more remote influences. In addition, there must be a thorough search through the daily life and habits of the patient, including diet, rest, exercise, work, worry and sex influences.

The ordinary methods of testing the soundness of the various body systems should be used. It is especially important to test the function of the kidneys, the rapidity of passage of food through the body, the urine, and the blood. Functional tests of the circulation must complete the picture. It is not enough to listen to the heart, and take the blood pressure sitting down. The blood pressure must be taken both lying and standing. Frequently hypertension is evident only in a recumbent posture. It is evidenced by the following cases which have hypertension lying down and no hypertension standing up. (1).

---

*Read before the Academy of Medicine, New York, November, 1921.

Case I.—Woman, aged fifty-three years, dementia.

	Systolic	*Diastolic*	*Pulse rate*
Horizontal	184	88	80
Vertical	100	70	82
Difference	—84	—18	— 2
Blood ptosis index			—135

Case II.—Woman, aged fifty years, diabetes.

	Systolic	*Diastolic*	*Pulse rate*
Horizontal	178	84	80
Vertical	88	50	96
Difference	—90	—26	— 16
Blood ptosis index			—165

EXERCISE.

In the past, exercise has been little used in hypertension, because of the relative unfamiliarity of physicians with its use. The ignorance of teachers of physical training of the application of exercise to circulatory diseases, coupled with the apathy and absorption of the patient, made it evident that it was safer to limit the patient's exercise than to venture into the dangerous unknown. These dangers exist.

The most evident risk lies in the increase in tension resulting from most common forms of exercise. A greater danger lies in the damage resulting from coincident fatigue or excitement. This damage is sometimes merely an excess of wear and tear which has gone beyond all power of the tissues to rebuild. Exercise is always a destructive process, though by exercise we desire to arouse a repair stimulus which effectively reconstructs the tissues, and makes them stronger.

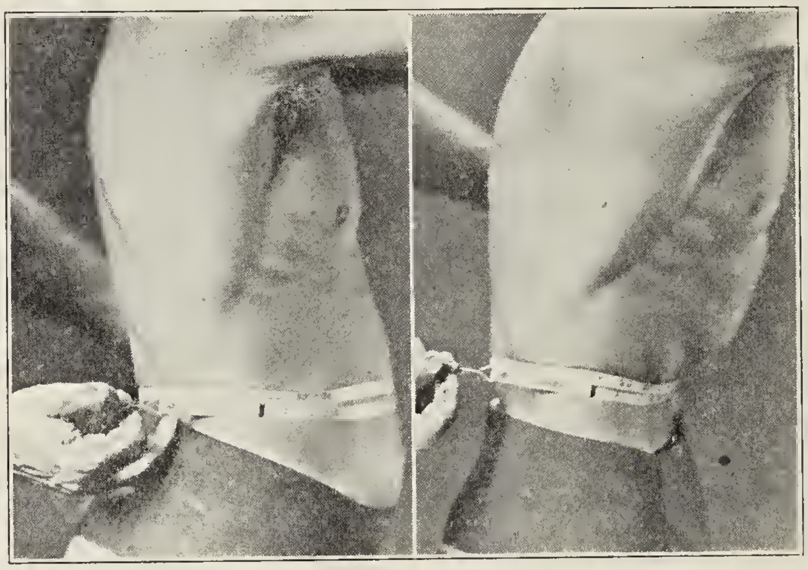

Fig. 1. Fig. 2.

Fig. 1.—Pumping, abdominal automassage by alternate contraction and relaxation of the abdominal wall.

Fig. 2.—Relaxtion.

In systems damaged by disease the repair process is itself sometimes injured, and its abilities impaired. The greatest harm that can come from exercise is a direct increase in the pathological process. This is most likely to occur because the pathological process is usually the best adjustment that a set of organs can make to counteract the damaging effects of some diseased conditions. A stimulus of any physiological process is often accompanied by a stimulation of a socalled pathological process, which is only a physiological process created to meet special diseased conditions. This is a conception of disease which is not in accord with the general textbook acceptation, which considers pathological processes as new and evil things. Muscular activity can be safely used in circulatory diseases, as a ship can sail a sea where the rocks and dangers are fully known and marked. Not only is it necessary to know the dangers of exercise, but its benefits and uses.

EFFECTS OF EXERCISE.

There are as many different exercises as there are different kinds of drugs, and their effects are almost as various. It is therefore absurd to ask the question, "What is the best exercise?" as it is to ask, "What is the best drug?" For convenience I suggest the division of the effects of exercise into the following eight classes:

			Most Typical Results
1. Local	Immediate	Mechanical	Muscular contraction — vasorelaxation
2. Local	Immediate	Chemical	Oxidation — Histamine, etc. produced
3. Local	Secondary	Mechanical	Increase in size — increased vascularity
4. Local	Secondary	Chemical	Food storage—decrease fat and waste
5. General	Immediate	Mechanical	Body massage and jar — blood pressure raised or lowered—
6. General	Immediate	Chemical	Transmutation and transfer of food waste and execretion
7. General	Secondary	Mechanical	Increased tone in all tissues—posture
8. General	Secondary	Chemical	Increased metabolism in all tissues

This table will serve as a provisional basis for the classification of the various forms of exercise, and an introduction of their therapeutic uses with particular reference to blood pressure.

VARIETIES OF EXERCISES.

There are five main varieties of exercises of value in hypertension:

1. Bed exercises. 2. Breathing exercises. 3. Anticonstipation exercises. 4. Contraptosis exercises. 5. Recreative exercises.

In addition there are others of importance including reduction of weight, psychic effect, etc.

The most prominent local, immediate mechanical effect accompanying contraction is vasodilatation. The dilatation of the vessels is calculated by Bainbridge (2) that the flow of blood through the active muscles may be from six to eight times greater than during rest.

This local effect of exercise creates therefore a larger set of chambers for the blood to occupy. If these changes occur throughout a large bulk of muscle, the additional amount of room provided for the blood can be very great. In this manner muscular exercise may be used to produce a marked lowering of blood pressure, at least twenty to thirty mm. in fifteen minutes' work. For this purpose slow, long-continued exercises of the muscles of the limbs, interrupted properly by periods of rest and relaxation, will produce best results.

Ordinarily, however, not only the local vasodilatation is elicited, but the general, pressor stimulation of splanchnic contraction and increase of heart output occur. Whether or not blood pressure rises or falls as a result of exercise depends upon whether the local vasodilatation effect on the muscles, overshadows the blood pressure raising action of the heart and splanchnics.

There are other or less important factors in operation (3). Bainbridge asserts that there is reason to believe that during exercise the products of metabolism in the muscle are not only a dilatation of the arterioles, but also of the tremendous capillary area. This is especially of interest because of the tendency of clinicians of late to believe that the constriction of the capillaries is the fundamental mechanical cause of high blood pressure.

We can make the capillaries and probably the arterioles dilate by the products of muscular metabolism; we can manufacture a natural vasodilator on the spot where it is most needed, and apply it directly. In other words, local exercise is symptomatic, endocrine therapy for hypertension (4).

This is a brief outline of the therapeutic use of local exercise of a large number of muscles, for reduction of high blood pressure. Whatever the scientific explanation may be, this type of exercise properly administered lowers blood pressure markedly for thirty to ninety minutes, and, in accordance the lowering of the pressure over a period of weeks improves the digestion, the action of the heart, and in some cases has apparently contributed greatly to a remarkable and decided recovery. A case of this type is reported as follows:

Case III.—Woman, aged sixty, complained of nervousness, pain over eyes, general disability. Blood pressure: horizontal, systolic, 210, diastolic, 110; standing, systolic, 190, diastolic, 110. Showed slight arterial hardening with no urinary findings, with the exception of a slight trace of albumin. The kidney functioned well. She was given rest in bed, a light diet and colon irrigations for four weeks, with symptomatic remedies applied, with little change in circulatory condition. Bed exercises were then undertaken. These were exercises of the large muscle masses undertaken slowly and quietly, and increased from five minutes every hour to eight minutes every half hour. A twenty-four hour prescription was written which included diet, rest, and diversion, and a gradually increasing general activity. Two abdominal exercises were soon added, the bed exercises gradually made more vigorous, and brought into longer and fewer periods, as invalidism was gradually left behind. The patient is now an active, vigorous society and club woman, with blood pressures running between 135 and 140, with a diastolic pressure between 80 and 90. The urinary picture is perfectly normal, and there is no suggestion of disease or disability, with the exception of a slight arterial thickening, and even this seems to be decreasing.

This is a common result in a typical case of hypertension approaching the structural stage. It illustrates also the general nature of the treatment.

The apparent return of hard arteries to their normal condition has been noted in four cases of a similar nature. Further report will be made. (The decrease of arterial fibrosis and the return of resiliency to the arteries will become an increasingly common experience, as our therapy improves. At present it is not only practically unknown but not expected. Eli Moschcowitz has reported in the interval between the reading and the printing of this paper a series of cases of acute nephritis following this course. The arteries, however, do not return to normal unless the patient as well as the disease is cured.)

The following prescription blank in use in one of the New York City hospitals gives an introductory series of exercises. It also illustrates the method of prescription, which includes not only the number of times, but also the rate, and emphasizes the necessary intervals of rest. This series is used not only in hypertension but also for those patients bedridden with valvular disease, myocarditis, diabetes, etc. A second series gives a more generous and vigorous set of exercises. To use the prescription the physician fills in the time for breathing, number of repetitions and rate, and makes the necessary notations in the directions at the bottom of the sheet. The conditions they indicate have proved adequate safeguards. It is necessary to have the exercises taught, but, once learned, little supervision is necessary. The best time for most cases is the first five minutes of each hour. In this and in all forms of exercise for hypertension, it is important to eliminate hurry. The movements must be leisurely. This is difficult but essential.

BED EXERCISES

Series A.

	No. of Times	Rate
1. Fist tight, open (flex, extend and separate fingers)	R. L.	
Rest Relax Breathing......Sec.		
2. Toes flex, extend and separate	R. L.	
Rest Relax Breathing......Sec.		
3. Smoothing Sheet—Wrist abduction and adduction	R. L.	
Rest Relax Breathing......Sec.		
4. Ankle Flex (emphasize) and extend	R. L.	
Rest Relax Breathing......Sec.		
5. Head Turning—Right and Left	R. L.	
Rest Relax Breathing......Sec.		
6. Hand Turnover (Pronation and supination)	R. L.	
Rest Relax Breathing......Sec.		
7. Foot Circle—Outward rotation at ankle	R. L.	
Rest Relax Breathing......Sec.		
8. Look up—Head extended backward		
Rest Relax Breathing......Sec.		
9. Hand to Shoulder—Flex and extend forearm	R. L.	
Rest Relax Breathing......Sec.		
10. Knee Raising (Flex knee and hip, foot to buttocks)	R. L.	
Rest Relax Breathing......Sec.		
	Total Time.....	

Exercises to be taken at .... A.M. every half hour, every hour. P.M., followed by rest of .... minutes.

Omit if patient is tired; if temperature exceeds 99-100.

Alternate right and left. Emphasize *complete* flexion and extension (unless painful to patient).

Exercises must be done slowly—there must be no increase in heart rate, breathing or blood pressure.

Breathing is deep, direct, i.e., chest lifted with inspiration, with no abdominal contraction.

Signs of Danger.—Sweating, palpitation, dilated nostrils, pallor, duskiness, corners of mouth drawn down.

Bed exercises are the simplest and safest of exercises for hypertension. Muscular exercise can also be performed by electrical stimulation, but this requires apparatus and tends to confirm the patient in his invalidism rather than to increase his ability. They are frequently better for the sanitarium than for the patient.

BREATHING EXERCISES.

There are four important results that may be obtained from breathing exercises: 1. To increase the mobility of the chest. 2. To increase thoracic aspiration. 3. To relieve abdominal stasis. 4. To give abdominal massage. Contrary to common report, breathing exercises are not of value in increasing the amount of oxygen in the blood.

TO INCREASE THE MOBILITY OF THE CHEST.

Hypertension most frequently occurs in those who are well along in years, and who, from lack of exercise, have never called upon the lungs for any vigorous activity. The chest wall becomes rigid. The expansion frequently is decreased to one inch or less. This rigidity is part of the general sclerosis of which the arterial hardening is but one expression.

In the normal, vigorous adult the chest acts as an auxiliary circulatory pump. It aspirates blood from the abdomen on inspiration and on expiration, throws it into the arterial system, causing a rhythmic rise and fall of blood pressures. When the chest is nearly fixed, this is diminished. Breathing exercises do good by reestablishing this rhythmic circulatory exercise. They can also do harm for they increase the arterial strain.

TO INCREASE THORACIC ASPIRATION.

When the chest loses its resiliency it usually hardens in a contracted state unless there is emphysema. It decreases in size while the abdomen usually increases, due to the constant effect of gravity upon the contents of the trunk and upon the chest walls themselves.

In a welltrained youth the chest is from six to twelve inches greater in circumference than the waist. In the halfworn adult, the reverse is most frequently the case and thoracic aspiration is reduced to a minimum. Breathing exercises of a certain kind can be used to increase the size of the chest as well as increase its mobility. This is a great advantage, in that the heart is given more room, and the circulation is unimpeded. The pressure of stomach and colonic gas gives less distress and is less dangerous in circulatory invalids. The aspiration of the thorax is increased, and the tone of the circulation is improved by the mechanical relief of the splanchnic circulatory stagnation which this affords.

RELIEF OF ABDOMINAL STASIS.

While the chest is raised and made more mobile, the aspiration of the thorax increases. This improves the upward drainage of both blood and lymph from the abdomen. The high chest relieves the abdominal contents of pressure of the organs attached to the chest and diaphragm, and decreases intraabdominal tension, and favors elimination. It thus helps the body bear the handicaps of high blood pressure and its accompanying conditions, and it helps to improve them.

ABDOMINAL MASSAGE.

Abdominal massage is one of the best results of the breathing exercise. In those forms of movement where the excursions of the diaphragm and abdominal wall are great, there is a large, marked, to and fro movement in the abdominal contents. This mechanically relieves stasis, and acts as a tonic, particularly to the intestinal tract, the liver, and the pancreas. It helps to remove the causes of intestinal autointoxication.

KINDS OF BREATHING EXERCISES.

There is a large variety of breathing exercises. There are over fifteen different useful forms. As a general rule, those exercises which give most movement to the abdominal contents and increase most effectively the thoracic aspiration are the best: One of the best breathing exercises is not breathing at all, but a see-saw movement which I call pumping, expanding and contracting the chest and abdomen alternately, but with emphasis on the thoracic expansion.

There is one important caution against the breathing exercises. In some instances they place too great a strain upon the heart and arteries. When the chest is lifted, it fills not only with air, but with blood. As it contracts, it squeezes out both air and blood. The blood must go to the heart. This sometimes causes heart strain. No breathing exercises should be given in cases of myocarditis without a careful testing of the heart. I have seen breathing exercises reestablish both auricular flutter and fibrilation during remissions of the regular heart rhythm. Breathing exercises have large and diverse values which have not been touched upon here. They will be made the subject of further report.

ANTICONSTIPATION EXERCISES.

Anticonstipation exercises fall into two classes. First, those which provide an abdominal automassage and stimulate intestinal activity, and second, those which by change of position relieve the intestines of kinks and pressures.

1. Automassage exercises.—Breathing exercises, it has been noted, provide an excellent selfmassage. In addition, abdominal bending or trunk bending forward and backward, right and left, and trunk twisting or a combination of these are useful. Exercises of this type which bring the abdomen in contact with the thighs, and particularly where the hands or fists are placed between the abdomen and the thighs to accentuate the effect, are useful. The army trench exercises and squatting exercises of all kinds belong in this category, but they raise pressures markedly. Selfmassage by the pounding of the fists of the patient or rolling a cannonball on the abdomen are useful, but are open to the same objection.

One of the most effective exercises for abdominal automassage is a circular movement of the abdomen. This exercise is best learned in the sitting position. The neck and sacrum are kept in place while the spine bends as the abdomen goes forward, left, backwards and right, describing a circle. This exercise is best illustrated by the movement of the hand in using a brace and bit, to bore a hole. While it is best learned in a sitting posture, it is most effective when done in the all fours position on the hands and knees. It will be made the subject of further report. It is used by William C. Adams, of Pompton, in the horizontal position, and called abdominal rotation, and in the sitting position in the hygienic ritual of an East Indian cult.

2. A change of posture from the vertical head up position to the trunk horizontal or the head down position works great changes in the intestinal condition. Very frequently we see an x ray picture of the transverse colon isolated by a kink at either end, under the liver and at the spleen. Small kinks occur in the sigmoid flexure. Placing the patient on all fours may straighten these out. Exercises such as rotation in this position will stimulate intestinal activity. There is a large variety of useful exercises of this type.

These two varieties of anticonstipation exercises are frequently exceedingly effective. The abdominal rotation and churning does not raise blood pressure materially nor do the simple exercises in the all fours position. The intoxication which is the basis of the high blood pressure is caused by intestinal position, and frequently a great improvement results. It is not uncommon for this combination of exercises to effect a cure in constipation that has resisted treatment for ten to fifteen years.

CONTRAPTOSIS EXERCISES.

Structural, visceral and blood ptosis are commonly found together in high blood pressure cases, due to the fact that inactivity, the most frequent contributing cause of high blood pressure, also causes weakness which permits gravity to pull down structures, organs and tissues of all kinds. The chest is small, the abdomen bulging, head hanging and the blood pressure is frequently from thirty to eighty mm. higher lying down than it is standing. (7).

Breathing exercises as indicated would help to reestablish proper tone. Exercise of the muscles of the back of the neck raise the head, and others strengthen and shorten the muscles of the abdominal wall and assist in raising the chest.

RECREATIVE EXERCISES.

The patient with hypertension should engage in the motor activities appropriate to his age, station in life, etc. Arteriosclerosis is an indoor disease. There should be a definite prescription of walking, golf, gymnasium activities, dancing, fishing; but in some cases the more vigorous exercises such as tennis and handball should not only be permitted, but encouraged. It is important that the patient should be given exercises which he likes or can learn to enjoy. Exercise that is not done has no therapeutic value. Companionship is of great assistance. Vigorous exercise frequently makes some patients much happier, and this contributes greatly to their welfare.

The patient should be put upon a twenty-four hour prescription, giving the proper adjustment of rest, exercise, meals and work. This will involve at first a careful analysis of the patient's history, interests and social conditions, as well as his physical and medical state. As soon as these conditions are ascertained, and the patient trained to do as he should, and he understands the reasons for this routine, he should be released from immediate supervision, otherwise he may be trained into the unhappy state of expert invalidism, a condition in which everything is seen in its bearing upon personal health.

PROPHYLAXIS.

Exercise has a large rôle in the prevention of conditions associated with high blood pressure. A good exercise program should include as follows: 1. Daily morning exercise with special attention to abdominal wall—twelve minutes. 2. Daily walk—three quarters of an hour to one hour (standard rate 120 steps to the minute—thirty inches to the step). 3. Three times in a week an hour of vigorous exercise preferably of the recreative character. 4. Once a week half a day to a full day should be spent in the open air.

In hypertension, depending upon the character and quantity of the exercise taken, and the associated pathological conditions, there may be expected a decrease in the diastolic pressure followed by the systolic, an improvement in muscular tone, circulation, nutrition, and psychological condition. There can be a great improvement in posture, and there is possibly reason to believe that the condition of the arteries and heart can be materially improved.

SUMMARY.

It should be recognized that various forms of exercise have different purposes and results. It is necessary to use this therapeutic procedure with just as much discrimination as one would use in prescribing drugs.

Exercise is a vasodilator and a reconstructive tonic. It is not a panacea. It should not be a fad. It will not replace the diet restrictions of salt, water or proteid, nor will it displace rest, salvarsan, or any other appropriate therapy. It has a place in the therapeutic program and its omission should be considered the exception and not the rule.

The author's references will appear in his reprints.

A Practical Method to Determine the Correct X Ray Dose in High Voltage Treatment*

By HANS HOLFELDER, M.D.,
Frankfort on the Main, Germany,
Assistant at the Surgical Clinic, University of Frankfort on the Main.

The chapter of modern, deep röntgen therapy has reached such dimensions that it will be impossible for me to touch upon more than the main points of the subject, omitting all discussion of the many details, so important in themeselves.

As is well known, the penetrating x ray treatment was first employed in a systematic way by the gynecologists of Germany. Their experiences with the method date back some five to six years, and have actually proved that x ray treatment in the hands of a skilled operator accomplishes as much, if not considerably more, than the bloody operation, in the treatment of tumors of the uterus.

The reason that gynecologists have been so much more successful with the deep x ray treatment than the general surgeon, is referable to two factors. In the first place, they are always dealing with one and the same organ; and secondly, this organ is most favorably situated within the centre of the pelvis, and is also accessible to direct examination. This fact greatly simplified and unified the physical problem. For so long as one succeeds in concentrating a symmetrical crossfire from various x ray cones upon the uterus in such a way that the centre of the organ receives the desired dose, one can be fairly certain of the equal distribution of the desired dose over the entire cancerous area. The problem in a way resembles the art of artilleristic sharpshooting.

For the surgeon, however, conditions are far more difficult and complicated. Aside from the differences involved in the biological problems the physical problem is also much more intricate. The tumors the surgeon is called upon to treat are often very extensive, they are seldom located centrally, in fact, generally excentrically, and different in every case. Frequently there are neighboring organs that are sensitive to the x rays and hence have to be protected against large doses. A permanent result can be expected only, however, if we are able to apply uniformly the x rays to every single point of the extensively ramified tumor region, so that no point receives either too much or too little. In artilleristic language, the problem of sharpshooting has thus become transformed into the difficult problem of freehand shooting.

---

*From the Surgical Clinic of the University of Frankfort on the Main. Read before the Clinical Society of the Lenox Hill Hospital, New York, November 11, 1921.

In view of the great diversity of conditions in every case, it is impossible to standardize the problem. Each case presents special topographical relations that have to be considered, and requires the formation of a separate plan. In order to do justice to these requirements, it is necessary that we free ourselves from long and cumbersome mathematical calculations. We have to find the ways and means that enable us to act in accordance with the needs of the individual case.

I am in a position to present, in brief outline, a method that has been evolved at the Surgical Clinic of the University of Frankfort on the Main under the direction of Professor Schmieden, the merits of which have been practically demonstrated within the past two and three quarter years.

The method enables the röntgenologist to obtain, within a few minutes, a plastic picture of the distribution of the doses within the body, and thus to form a plan that seems best suited to the case in hand. The description of *Felderwähler,* that is, field selector, was presented in October, 1921, and was published in extenso, with illustrations, in the *American Journal of Röntgenology.*

I should like to add a few words regarding the practical results obtained with this method. The period of observation is, of course, entirely too short to speak of permanent results and the early results so far obtained are by no means uniformly favorable. We still have a certain number of cases which we are unable to benefit. But we also have another series in which the results have been actually amazing, showing beyond a doubt the great superiority of this procedure over the old, inexact x ray methods, and we, therefore, feel that we can conscientiously recommend the method for general trial.

Particularly striking have been the results that we have observed in the otherwise absolutely hopeless cases of bone and liver metastases. We have seen spontaneous fractures healed within a remarkably short time. We have on record several cases of definitely proved liver metastases, secondary to carcinoma of the rectum, that have completely healed, clinically. We have one case of liver metastasis, fully the size of a man's head, following melanosarcoma, in which the patient became entirely well and was able to work, two and three quarter years after treatment—a result which, to my knowledge, has never been achieved with any of the older methods in this most malignant type of tumors. It seems that our exact technic is capable of producing better results in cases of metastases than in primary tumors. In the latter, the technic of radium emanations, as worked out in America, seems to attain better results. I have seen primary tumors so markedly influenced by emanation implantation at the State Cancer Institute in Buffalo, that it is my firm conviction a combination of our x ray technic and the American emanation implantation will become the method of the future.

Now, as to the question of drawing the dividing line between the surgical operation and x ray treatment: I wish to emphasize that at the Schmieden Clinic we do not consider it justifiable to subject to the x rays —a method still in the evolutionary stage—a truly operable carcinoma, but invariably resort to the surgical operation as the method that has been fully perfected and tested. However, we believe x ray treatment in conjunction with the surgical operation to be of great value.

When it comes to operable sarcomata, however, our position is different. Seitz and Wintz found thirty-three per cent. of the patients reported cured by the x rays to have remained well for three years, and a preliminary survey of our own cases promises results at least as favorable. It appears, therefore, that the patient's chances of a cure by x ray treatment are fully as good as those treated by the surgical operation, while he escapes all mutilation. In view of these facts, we have ceased, at the Schmieden Clinic, to attack sarcoma of the extremities with the knife, but apply the röntgen rays instead.

The foregoing will give a fair idea of the rules followed at the Schmieden Clinic as regards the technic in the application of the röntgen rays. Since the method has not been tested sufficiently long, it may be well to limit somewhat the indication for its use at this early stage.

As the most important advantage of our method we consider the fact that it enables the trained röntgenologist to form an exact plan of treatment, adaptable to the particular topographical conditions present in the given case. The determination of the doses in deep x ray work has thereby been greatly facilitated.

Permit me, in closing, to make a few personal remarks:

After a three months' sojourn, I am about to leave this wonderful country, to return to my work in Frankfort on the Main. Owing to regrettable external circumstances there has been an interruption of scientific intercourse between our two countries for six years. Through your extraordinary hospitality I have been given an opportunity, as one of the first from abroad, to become acquainted with the progress of American science within this period. As different as the external conditions have been under which the evolution of the sciences of both countries have had to progress, so also has been the direction in which the advances have been made. The scientific joy which I have experienced in the study of the interesting progress made in America, is difficult to describe. If I have succeeded by the demonstration of what we have been doing abroad in arousing, in turn, within you if only a slight degree of that scientific joy, I shall be very happy indeed.

Let me thank you most sincerely for the splendid hospitality that has been extended to me while in your country; and let me add the statement that whosoever may come to Europe within the next years, in order to inform himself on the work that has been done there, he may be assured of a most hearty welcome at the university and especially as the guest of the Schmieden Clinic.

The Use of Static Electricity in the Treatment of Noninfected Inflammation

By WILLIAM BENHAM SNOW, M.D.,
New York.

The time is not long since, when the static electric methods were tabooed and rated, by some, as tolerable methods for effecting psychic influence upon emotional individuals. The theorists labored under that impression, and the notion that it exerted no material influence upon underlying internal structures. Until the works of Humphris and Turrell were published foreign authorities had contributed little to the recent literature of the static modalities. The Germans and Austrians have never contributed anything of note on the use of the static methods. The French authorities admit the neglect of the static methods, and the French machines are inadequate for producing the necessary effects to carry out the treatments to be here described.

To the American investigators must be accorded the credit of developing this, now well established, department of electrotherapeutics. Morton's currents and his lucid exposition and persistent effort at development of means and methods laid foundations upon which the science and modern methods have been established by himself and his students.

With those who are familiar with all electrotherapeutic methods the use of the static methods fills an indispensable place in medical practice, accomplishing what no other physical or other method can replace or supply.

In the scope of this paper it is only possible to outline the characteristic effects and give a general consideration of the ways in which the electrostatic methods are made to influence and restore normal processes.

First of all, and throughout the consideration of the subject, the static methods must be recognized and treated as mechanical measures, producing no electrolytic effects as are produced by the galvanic current—the directional or constant current of larger amperage. The static current flowing with opposite polarity from the two poles of the static machine is a direct or constant current of very high voltage, but of infinitely small amperage; the current strength varying from one tenth of a milliampere in the smaller machines to a maximum of seven milliamperes from the most powerful high speed static machines that have been built.

Currents having these qualities possess properties that are distinctive, and the static current in particular, from the manner of generation has other unique qualities, in which it differs from all electrical currents from other sources, which renders it impossible to duplicate the same results from other apparatus.

Its effects upon animal tissue is unique in that it individualizes the tissue cells regardless of the nervous mechanism, causing the muscle cells to contract independently of the nerves, as does the constant—the galvanic—current of low voltage. The galvanic current when applied with interruptions will cause detached muscle cells to contract (1). While the galvanic current, of low voltage, must be applied directly to the muscle mass and interrupted to produce such contraction, the static current of great voltage and small amperage will induce the same effect upon the tissues beneath the integument and layers of fat and without injury to the most delicate structures. Herein lies the advantage of the static modalities, effecting, as they do, contraction of the collections of cells that constitute the muscle mass independent of the neuromuscular mechanism.

When contraction is induced in this manner in swollen infiltrated tissues the effect is to relax the tension of the muscles and force out or express the exudations from the lymph spaces, on through the lymph channels, and thus remove the accumulations of waste matter from the tissues. This is readily demonstrated by the depletion with softening and removal of the swelling from the tissues which follows the scientific use of the static modalities or methods of administration.

The effort to attempt to remove foreign exudates by inducing contraction by stimulation of the neuromuscular mechanism at motor points with other electric currents are futile, as is readily demonstrated by the contrast of clinical results from the employment of other methods as compared with the strikingly successful depletion by the direct stimulation of engorged tissues with the static methods.

Based upon this principle the static current fills an invaluable place in the treatment of noninfected inflammation and in activating dormant conditions, which it is impossible to accomplish in other ways.

The generally accepted notion, that inflammation is a tissue reaction following trauma, or any severe local irritation, seems on the contrary, from the facts observed, rather to be a condition in which the influx of blood is so excessive that stasis is established with complete inertia from too great an influx of blood induced in the tissues involved—the result of an unnatural cause. The call for repair of damage done results in a profound tissue engorgement with the normal processes *hors de combat*. Such is not reaction, but inertia—with the presence of pain due to pressure—a condition which tends to persist indefinitely and results, if not relieved, in the varying degrees of hyperplasia which will result in what is designated chronic inflammation, or, without a correct recognition of the original cause, is very often dignified by the erroneous term—chronic rheumatism.

There is a great and extensive field of indication for the administration of the static methods which will promptly displace the exudations, the local stasis —a large and important field which is indicated for the relief of all inflammatory conditions in which infection is not present, and would so be scattered, or in cases of fracture when the muscular actions induced would displace the parts. No other known methods succeed so well if at all in the conditions mentioned.

When massage or manipulation is applied to acutely inflamed conditions it increases the inflammation; whereas, the static modalities relieve it by removing the exudation, and there is no comparison in the benefits derived. Massage works and irritates a part, while the static modalities make the parts work, and so relieve the swelling and tension, without irritating the sensitive tissues.

The treatment of a sprained ankle, a condition which is completely relieved, and uniformly within five days, oftener in three days if it comes under observation the day or day following the accident, will well illustrate the *modus operandi,* and general result of static administrations.

Case I.—Mr. T. sustained a severe sprain of an ankle joint at his home in New Jersey, injuring it so severely that he came to town on crutches and to our office in a taxicab. The ankle over and around the internal malleolus was much swollen, and any movement of the joint was very painful. Metal electrodes were applied to the swollen parts, and the static wave current administered with a regulated spark gap for twenty minutes. The static brush discharge was then applied over the more sensitive and ecchymotic areas, where blood had escaped beneath the skin from rupture of the small vessels in the injured parts. The application was continued until considerable infiltration was removed as evidenced by the relief from pain and softening of the tissues. The patient could then move the joint with little pain, but there was still marked stiffness and a sense of heaviness due to tension of the muscles of the leg and foot that crossed the joint, and considerable infiltration in the deeper tissues around the malleolus. Indirect static sparks about one inch in length were then applied to the deeper parts and to the extensor and flexor muscles of the leg from the knee to the ankle joint, and of the foot until the tension of the muscles was entirely relieved and the ankle could be moved without tension or pain.

The effect of the static sparks and static wave current in removing or relaxing muscular spasm present with all inflammatory conditions is remarkable and beneficent, for otherwise as in all cases of traumatic arthritis the relief would be but partial; whereas, as in this instance, the relief was complete. The treatment had consumed about one hour of an operator's time, but the relief afforded was the reward, the patient returning to his office by public conveyance, with his crutches in his hand, and without pain or disability.

Applications of the brush discharge on the two following days, to complete the absorption of the ecchymosis and sparks, as on the first occasion, and the cure was complete.

The details have been given at length in this case as illustrative of a complete technic in the treatment of traumatic arthritis. This technic with some slight modifications is applicable to the treatment of arthritis in every joint of the body. As a rule, however, except in the treatment of the ankle and small joints of the hands, the static brush discharge is not required.

Many sprained ankles have been cured by me during the past twenty-five years in an average time of three days. In but two cases has there been any rupture or fracture of the other joint structures. In these, with torn ligaments, a removable plaster cast was adjusted to the limb and foot and frequently removed for static treatment, a complete cure being effected in six weeks, during which time the patients wore the plaster splints and were otherwise unrestrained. One, a chauffeur, after the first week resumed his work without discomfort or seeming impediment to his complete recovery.

Case II.—Mrs. G., another case of sprained ankle, illustrates the surgeon's method and the general attitude as to the prognosis in these cases. Mrs. G. sustained a severe sprain of her left ankle and consulted a distinguished young surgeon, who had served in the Great War. He told her that she had ruptured a ligament and that it would be many weeks before she could play tennis. He strapped the ankle in the usual way of the surgeons. At that time she told him that she thought she knew where she could get more prompt relief. She came four days after the accident and was completely relieved after six days. The result demonstrated that there was no injury to the ligaments other than strain.

Case III.—Mr. M. P. The following case will illustrate the results in the treatment of traumatic injury of the knee joint: The patient while playing golf accidently dislocated his knee joint and was referred to us for treatment. He came in a disabled condition with pain and swelling of the joint and tension of the muscles of the leg and thigh. The wave current was first applied to the joint, after which long sparks were administered to the openings around the joint and up and down the muscles of the leg and thigh, avoiding the bony prominences, until the pain was relieved and the patient stepped from the platform, and said that it was a miracle. It was not, but the usual relief that we are able to give in these cases was afforded the patient. One additional treatment on the following day and the relief was complete.

Case IV.—Captain K., M. C., while riding a horse at Camp Merritt, was thrown from his horse falling upon his right shoulder. He sustained a severe contusion of the shoulder without fracture. At that time he had been investigating physical therapeutic methods and came in with his arm bandaged to his side in a helpless and extremely painful condition. The static wave current was applied over the shoulder where the injury had taken place followed by the static sparks over all of the tense muscles in the region. Following the first treatment he was able to move his arm and wear his coat when he returned to camp. He received but three subsequent treatments when the parts were normal. This removed from his mind every element of skepticism concerning the therapeutic advantages of the static modalities.

In cases of arthritis that have been neglected for two or three weeks, it takes much longer to relieve the condition. Uniform success, however, attends the static treatment when only a sprain or strain is the occasion of the trouble.

The following cases will illustrate the results obtained in the cases of sacroiliac subluxations—one of the most common accidents that occur—so common that within a year upwards of fifty cases have been treated in our office, and with success.

Case V.—Mr. G. dislocated his right sacroiliac articulation while playing polo. He came into the office so disabled that he required assistance to get up and down steps and on the insulated static platform. The referred pain along the course of the sciatic nerve and down the crural nerve was severe, due to the irritation of the branches of the lumbar plexus that make up these great nerve trunks, where they cross the sacroiliac synchondrosis. In fact most of the patients who apply for treatment complain of sciatica or call it lumbago, and come for treatment of those conditions.

The static wave current was applied over the gluteal muscles and across the back with two twenty minute administrations, employing an electrode of soft metal four by ten inches first across and over the quadratus lumborum and psoas muscles and then over the synchondrosis and glutei extending below and including the sacrosciatic notch where the sciatic nerve emerges to relieve the local infiltration over the synchondrosis and the tension of these muscles, which hold the bones fixed in displacement. The application over the latter parts is attended with severe pain if the spark gap is not regulated to toleration. Having relieved the tension the next step is to restore the displaced bones of the joint to their normal position. This can either be done by extension or manipulation. When the displacement of the ilium is downward—the most common displacement —place the patient on an operating table with his back to the operator, lying on the side not involved, with his legs slightly flexed. The operator then exerts pressure with one hand upon the ilium, after relaxing the muscles by firm pressure; pressing the ilium downward makes a sudden impulse downward. At the same time with the other hand the shoulder rotates in the opposite direction. By thus using both hands one resting over the crest of the ilium and the other rotating the body backwards, it is as a rule possible with cases treated early to reduce the displaced bone with the first effort. In cases in which the displacement is downward, as most of these cases are, the next move that is employed is to flex the leg and thigh and force the thigh well up on the trunk, and then turn the knee outward, rotating it downward gradually and extend; employing practically the same method as in replacing a dislocation of the hip joint. Then flex the knee and thigh upwards with the hands on the leg and give it one or two sharp jerks, extending the thigh and leg down. In recent cases this last maneuvre will often suffice to replace the displaced joint.

When the static wave current has been applied first to relieve the muscular spasm the reduction in severe and neglected cases is rendered possible—the muscular contraction of the powerful thigh muscles otherwise offering too great resistance. After the manipulation for reduction, it is customary to apply long static sparks to the involved muscles to insure against recurrence of contraction, which may, and often does, throw the part back in displacement when the static current is not employed.

The patients are instructed to exercise three times daily, lying upon a hard surface and raising the body in the opisthotonos position with the shoulders and heels resting on the floor, performing this exercise as first suggested by Dr. Frank E. Peckham, a few times after each interval to maintain the muscles in a relaxed condition.

Mr. G., following the replacement, with the daily static treatment and exercises, as outlined, made a steady improvement and complete recovery and within twelve days was able to play polo.

Case VI.—Mrs. M., another case, will illustrate the results in a chronic case of sacroiliac luxation. She had been suffering from pains in the lower back and thighs for several months. For relief she had consulted many physicians in the South and had been referred to New York. In the opinion of the physicians who examined her at Bellevue Hospital the suffering had been considered as due to trouble in her kidneys and bladder and she was referred to Dr. Edward L. Keyes, Jr., who referred her to me as a case of arthritis involving the lower back region. A sacroiliac luxation was readily diagnosed from the tenderness over the synchondrosis, and her inability to raise the right leg on the affected side while lying upon the back. Great tenderness was evinced when the static wave current was applied over that articulation, as in the previous case. Pain at this point when thus caused is characteristic of a sacroiliac luxation. This patient was treated by the method described in the treatment of the previous case and made a prompt improvement, and though she had been suffering from the condition for many months was cured within six weeks, and returned to her home in the South.

Case VII.—Mr. M., a laborer, was loading empty ten gallon oxygen tanks on a truck. Grasping one unsuspectedly filled with water he induced a luxation of the joint. He was brought to our offices in an all but helpless condition by a man who was with him, and the diagnosis was readily made of a sacroiliac displacement. The man was given the static treatment over the region of the ilium, and long static sparks, as described, and an effort was made at reduction by extension of the leg, but at first without success. He was able, however, after the treatment, to go to his home, ten miles away, by public conveyance and returned to the office in five hours; indicating the marked relief obtained from the static treatment, even with the displacement not completely reduced. The displacement was reduced the same day, when he returned, and on the following days two additional treatments restored the parts to normal. Prompt relief is thus obtained in all cases that come under observation immediately following the accident.

That the static wave current plays the most important rôle in the treatment of sacroiliac subluxations has been shown in my experience from the fact that for ten years cases of sacroiliac luxations had been relieved and successfully cured by the static wave current and sparks without the methods of adjustments, as outlined, except by Dr. Peckham's method of exercising the body in the opisthotonos position while resting upon the heels and shoulders as previously described. The following cases will illustrate the method and results:

Case VIII.—Dr. McK. came to my office with a painful condition in the leg and thigh caused by a sacroiliac luxation, which was readily diagnosed by placing the patient upon his back on a table, when he gave the characteristic indication of Goldthwaite, being unable to raise the heel on the affected side from the table. In this instance the pain was so severe that he could barely instigate a movement. The static wave current was applied to the affected side and caused the characteristic pain over the part. It was followed by the application of long static sparks over all of the local muscles. He left the office in a fairly comfortable condition and returned the following day reporting little discomfort in the interval. The same routine was carried out as on the previous day and the Peckham exercises were begun. He came again on the third day and showed marked improvement. He left the office with no discomfort and with an appointment to come again in two days. He did not keep his appointment, but ten days later called me on the telephone and told me that he had been busy and had had no pain since the last treatment and did not think that more treatment was necessary, as he was cured.

There is no class of cases in which the static wave current plays a more important and useful part than in the treatment of sacroiliac luxation.

Neuritis is another painful inflammatory condition in which the static modalities are the preferred methods. The referred pains of neuritis often mislead physicians and they are likely to apply lotions and liniments over the painful spots without reference to a local lesion. Whereas, in cases of brachial neuritis if a metal electrode is placed over the shoulder, a place of severe tenderness will be located somewhere over the branches of the plexus, which will locate the lesion. An application of the static wave current will elicit much pain over the region so located and the patient will endure but a very short spark gap, the dose given being measured by the length of the spark gap in the treatment of all painful conditions. When these patients are treated at the onset, only a very few treatments with the wave current and sparks will be required to effect a cure. If the case is of toxic origin, however, as we find about ten per cent. of cases to be, a longer time will be required to remove the condition, when added strict attention must be given to removal of local sources of focal infection. If a case of neuritis or any other inflammatory condition that is allowed to persist for two or three weeks before treatment is instituted, whatever the cause, it will take considerable time to effect a cure on account of the adhesions and hyperplasia that will have taken place. If the patient will agree to persist in neglected cases, however, a good prognosis can, as a rule, be given.

The following case report will illustrate the characteristics of both the neglected cases, and those receiving prompt attention.

Case IX.—Mr. H. came suffering from a chronic neuritis of several months' standing and at first the improvement was marked to a certain state of improvement, after which persistence for three months was required before the trouble was finally conquered by the static treatment. The same patient called on the telephone ten years later to say that he had a severe case of neuritis, and could not dress himself without assistance. He was able to get to the office, however, and was completely relieved by the first treatment of the pain, which had prevented sleep the previous night and the disability was relieved. Two more treatments with the regular routine method with the wave current and sparks as described effected a complete relief and cure of the condition.

Sciatic neuritis, tic douloureux, herpes zoster and numerous other cases of localized neuritis are successfully treated on the same general principle.

The whole list of inflamed conditions in which the electrostatic modalities perform effective services have demonstrated the effectiveness of these important measures.

Wherever infiltration exists in the body, as in hypertrophic cirrhosis of the liver, malarial enlargement of the spleen or disturbed metabolism of the pancreas, as of the uterus or prostate gland; in all conditions, not characterized by the presence locally of infection or malignancy, the results obtained by the use of the static modalities have an established place in the therapeutics of all such conditions, as also in spasmodic conditions occurring with noninfected inflammation in all parts of the body in which they afford relief that cannot be obtained so well from other sources.

The static modalities play a rôle as compared with massage which replaces it in the treatment of contracted muscles. This is due to the fact that the static current causes the muscles to work and so removes the tension, whereas massage works the parts. Both from the point of view of depleting and removing the tension and improving the nutrition the static methods are superior to massage, except in cases of bone fracture for the relief of which reflected incandescent light and heat is better than either.

CONCLUSIONS.

1. The static current is a direct or constant current of small amperage and high voltage, and produces practically no electrolysis. The effect of the current is essentially mechanical.
2. The static modalities affect the muscle cells beneath the skin and layers of fat inducing independent contraction as the constant current of low voltage does when applied directly to live or dead muscle tissues.
3. The distinctive property of the static modalities, from the character of the action upon the muscular and elastic tissue structures, a, cause drainage or expression of exudations as present in conditions of stasis in the lymph spaces through the lymph channels, thus restoring circulation and repair, and, b, relieve muscular spasm when present, and are indicated in all cases except when infection is present.
4. The essential property of the static current is such that it is indicated for the relief of all cases of noninfected inflammation and for the improvement of general metabolism.

X Ray Therapy in Exophthalmic Goitre

By SINCLAIR TOUSEY, A.M., M.D.,
New York.

FREQUENCY OF THE DISEASE.

Cases of exophthalmic goitre are very numerous, as evidenced by the fact that a surgeon in another city performs surgical operations on perhaps eleven cases in a single day, and also by the fact that I have half a dozen cases under treatment at the present time in my private practice. But there are numerous persons with or without noticeable goitre whose lives are marred by the effect of disturbed thyroid secretion. A man of good intelligence lacking only in initiative or "pep" may acquire that mysterious quality and achieve professional or business success following the discovery and remedy of thyroid disease. And many a woman with a pulse of 90 to 120 and a general condition of invalidism becomes well and strong. The cases which are most certain to be recognized and referred for appropriate treatment are those which present the typical symptoms of Graves's disease: exophthalmos, which may be slight; pulse of about 120; palpitation of the heart; tremor so pronounced that it is difficult to pour out a cup of tea without spilling it; debility, varying from nervous prostration to severe toxic symptoms; and thyroid enlargement, which may be slight.

CAUSATION.

There are many cases in which a nervous element seems to be responsible, as when several young women at the same school manifest it at the same time. Many cases follow the birth of the first child. Other cases seem to be dependent upon the quality of the water or food; for example, a deficiency of iodine. The prevalence of goitre in Switzerland has always been attributed to snow water. I always make radiographs of the teeth and in some cases very marked periapical infection is found. In one of the cases now under treatment three unerupted and impacted wisdom teeth have pressed against the roots of the second molars and caused them to grow in a bent shape. No attacks of pain occurred but I am sure there was nerve strain and this may have had a causative relation to the exophthalmic goitre. And in this particular case there was mental disturbance which made the cure of both dental and thyroid lesions imperative. Syphilis is one of the causes and these cases require the local treatment for exophthalmic goitre as well as the constitutional remedy.

DISTURBED THYROID FUNCTION.

Disturbance of thyroid function naturally divides itself into hyperthyroidism and hypothyroidism; or into excessive and insufficient thyroid activity. Cases of exophthalmic goitre, meaning rapid pulse, some thyroid enlargement and protrusion of the eyeballs, may have either hyperthyroidism or hypothyroidism and some cases begin as one of these disturbances and change to the opposite. In excessively fat persons, insufficient thyroid secretion is often present without exophthalmic goitre. And of course an absolute lack of thyroid secretion or complete extirpation of the thyroid gland is incompatible with a state of health, myxedema being one of the consequences. Cases of exophthalmic goitre with hyperthyroidism might be expected to be distinguishable from those with hypothyroidism by such symptoms as greater intestinal activity, normal perspiration and clear complexion in hyperthyroidism, contrasted with sluggish digestion, muddy looking skin, and absence of perspiration in hypothyroidism. But as a matter of fact such symptoms do not always enable one to decide the question, and as the required x ray applications are different it is quite necessary to test the matter.

TESTING FOR HYPERTHYROIDISM OR HYPOTHYROIDISM.

This is accomplished by me in various ways. Administering iodine aggravates the symptoms if the case is one of hyperthyroidism and so does the administration of thyroid extract. The test need last only a day, the results being prompt and transitory, with no bad aftereffects. The pulse which was about 84 may go beyond 100 during a single day's administration and return to 84 the next day, when the iodine or thyroid extract is stopped. If there is no aggravation of the symptoms a considerably longer test with iodine or thyroid extract may prove that its effect is beneficial, and it may be used as an adjunct to the regular course of treatment in a case which this test indicates to be one of hypothyroidism.

Another test is the administration of pituitary gland. This has a specific effect, relieving the symptoms of hyperthyroidism almost as promptly as iodine or thyroid extract aggravates them. I have observed little or no immediate effect upon cases of hypothyroidism.

In a case which was thought on general principles to be probably one of hyperthyroidism, if the pulse was in the eighties or nineties and I was going to use a medicinal or endocrine test, it would probably be thyroid extract, at least at the start, and in case of an aggravation of the symptoms a subsequent test would be made with pituitary. If, on the other hand, the pulse was 110, 120, or more, and this kind of a test was to be made, it would doubtless be with the pituitary, because of the probable hyperthyroid nature of the case and the greater desirability of a favorable rather than of an unfavorable reaction.

My favorite test is the measurement of the basal metabolism. An increased metabolic rate is present in hyperthyroidism. It requires preparation by fasting for twelve or fifteen hours and the apparatus and technic are elaborate, but the test itself causes the patient no inconveniences or discomfort and there is no aggravation of symptoms whatever the nature of the case may prove to be. It is employed whenever practicable, except when a short cut toward the selection of a medicinal or endocrine adjuvant to the x ray and electric treatment is desired.

THE THYMUS GLAND.

This gland often seems to be concerned in exophthalmic goitre; and in cases of hypothyroidism it is my custom to apply the x ray to the thymus as well as to the thyroid.

SIMPLE TUMOR OF THE THYROID GLAND.

This is a different disease from exophthalmic goitre. Some of these tumors yield to x ray or radium treatment and some are very resistant. In the latter cases I employ radiation as a first aid and advise operation as a last resort. This is in marked contrast with my feeling regarding exophthalmic goitre, for which I consider radiation and medicine or endocrine therapy as usually the complete treatment, and I have often been called upon to employ these measures after the failure or incomplete success of surgery.

CASES IN WHICH SURGICAL OPERATIONS HAVE BEEN PERFORMED.

There may have been a ligation of the inferior thyroid arteries or a removal of some part of the thyroid gland; or in some of my cases both of these operations have been performed before the case was referred to me. The continuance of the rapid pulse, exophthalmos, slight enlargement of the remaining part of the thyroid gland, and a condition of invalidism has called for x ray, electrical and endocrine therapy, and even in these cases the patients may be restored to health and strength.

PRINCIPLES OF X RAY THERAPY IN THYROID DISEASE.

It is especially desirable that the skin shall not be affected because of the number of applications and the time over which the series of treatments sometimes extend. Any effect upon the skin might have a permanent aftereffect. To secure an effect upon the thyroid gland without an undesirable effect upon the skin, the x ray should be of considerable penetration. It should correspond to a long spark and be filtered so that practically no rays are applied which would be entirely arrested by the skin without beneficial effect upon the thyroid. The exact wave length of the x rays or the equivalent spark length is unimportant. All x rays that reach the thyroid have a specific effect upon it and I have cured cases with rays varying from a four to a twelve inch spark. I have never sought to obtain a cure by a single massive dose of x ray or radium, as is so often done with fibroid or malignant tumors in other regions.

The effect sought in cases of hyperthyroidism is to cause a fibrosis of part of the excessively active and more or less overdeveloped glandular lymphoid tissue. This is similar to the result of x ray applications to a tuberculous lymphatic gland. There is usually a reduction and very often a marked reduction in the enlargement but the special object sought is not to secure absolute disappearance of palpable or visible evidence of the thyroid gland. The desirability of leaving the requisite amount of properly functioning thyroid gland is an important reason for accomplishing a cure gradually and not by a single dose which might possibly be overestimated. Three applications a week result in progressive reduction in the pulse rate and improvement in appearance and all other symptoms. It is my custom, in a six weeks' course of treatment, to apply the dose of x ray which I know will not affect the skin and then to have an intermission during which the x ray is not applied but other forms of electricity, with or without endocrine therapy, may be given. At the end of six, eight, or ten weeks the x ray treatment is sometimes duplicated, or in some cases the subsequent applications are made one, two or three weeks apart. The electrical treatment usually employed as an adjunct is the rhythmic static wave current applied to the thyroid for fifteen minutes and to the epigastrium for twenty minutes. The dose of the x ray must be left to the judgment and experience of each operator and if I mention my own it is not as a prescription to be implicity followed by others. My patients are at present receiving six minute applications over a four by five inch area, at a distance of sixteen inches from the anticathode through six millimetres of wood in contact with the skin, and half a millimetre of zinc and two fifths of a millimetre of aluminum near the x ray tube. The current traversing the tube is two ma. and the equivalent spark is eleven and a half inches, equal to a voltage of 170,000. A total of one hundred minutes is applied in six weeks.

Cases of thyroid hypertrophy, in which there is a normal pulse, no noticeable tremor, but with Graefe's sign, the upper eyelid not following the movement of the eyeball downward, and with every probability of the development of the other symptoms of Graves's disease or exophthalmic goitre, should receive the treatment outlined above.

THE TREATMENT OF HYPOTHYROIDISM.

The extreme cases of myxedema require thyroid extract at first. But even from the first, stimulating doses of the x ray are applied to the thyroid and to the thymus; and the static wave current is applied to the thyroid and diathermy to the liver, kidney and adrenal glands. From a suitable high frequency apparatus one terminal is connected with a metal sheet electrode five inches square, or larger, in contact with the skin over the front of the liver, while the other similar electrode is over the region of the right kidney. A current of 1,100 or 1,500 ma. is applied for thirty minutes or less. This would reduce the blood pressure in cases of high arterial tension, but it usually does not reduce it in cases of low arterial tension. The diathermy promotes natural liver and intestinal function and very often these patients get rid of the habit of requiring a laxative. The stimulating dose of x ray applied by the author has the same factors as already detailed, except that a total of only about twelve minutes a month is applied to the thyroid and sixteen to twenty-four minutes a month to the thymus. In the ordinary case of hypothyroidism there are noticeable enlargement of the thyroid, anemia, and general debility, with or without rapid pulse.

ENDOCRINE THERAPY AS AN ADJUNCT TO X RAY AND ELECTRICAL TREATMENT.

The whole gland pituitary is used in the diagnosis and treatment of hyperthyroidism and thyroid extract is similarly employed in hypothyroidism. It should be noted that all my earlier patients were treated with the x ray alone, including one of the two detailed herewith who have remained well for eighteen years after a single course of x ray treatment. But endocrine therapy certainly has been a help. In some cases of thyroid dysfunction it constitutes the whole treatment, in others it is combined with static electricity with or without x ray. In still other cases great improvement has been obtained by the x ray and electricity and the frequency of these applications has been reduced to once in two or three weeks but still the patient is not quite well. Then the endocrine products combined with the x ray and electricity complete the cure.

CASE REPORTS.

Case I.—Mrs. B., aged thirty-two years, came to New York on September 14, 1905, from her home in Wilmington, N. C., accompanied by her physician, Dr. I. N. Love. There was slight enlargement of the thyroid gland, well marked Graefe's sign; pulse never below 120; such palpitation of the heart that it shook the bed; such tremor that she could not pour out a cup of tea, and great debility. X ray and high frequency treatments were given three times a week during September, October and November, and the last three treatments in December, with progressive improvement in the pulse, which was reduced to 90, and in other symptoms, and at her earnest solicitation she was allowed to go home during December, 1905, in time for Christmas. But this was only on condition that her physician should make daily reports on the pulse and other symptoms and that she would return for additional treatment upon receipt of a telegram. During the eighteen years that have elapsed no treatment has been necessary and she is in robust health.

Case III.—Miss W., a patient of Dr. C. Graham-Rogers, came to me on November 9, 1915, with slight enlargement of the thyroid gland, Graefe's sign, moderate tremor, pulse 112, palpitation not marked. The goitre was soft. Following my custom, I made radiographs of the teeth, which revealed marked apical infection of two lower molars. An effort to save these I believe delayed the cure by the x ray and high frequency currents, from November 9 to May 7, but this was affected and a few years later (August, 1918) she had remained perfectly well.

Case VI.—Mrs. P. was referred to me on March 31, 1922, by Dr. E. O. Lindenmuth, of Indianapolis, who gave the following history: Goitre came on gradually nine years ago, when the patient was in California under treatment for kidney trouble. She was operated upon one year ago in July. Pulse was 160 before operation and 120 afterward. She had a number of x ray and electrical treatments and felt better; sometimes her neck would look smaller and she felt stronger; she had been weak and nervous before the x ray treatments, and her pulse went down to 92 and 90. Her last x ray treatment, given in Indianapolis, was in October, and in March, when she came to me, radiographs of her teeth were normal; tonsils had been removed, as they had been found to be as a source of infection. When she exerted too much her heart skipped a beat, but after resting became better. The pulsation in the throat had not been noticeable nine years before. Blood tests did not show too many white corpuscles; last test was in October. A previous test with thyroid extract showed deficient thyroid secretion. She had had attacks of biliousness, her skin becoming greenish brown in color, but after the administration of laxatives would again be normal. Had one of these attacks on March 31, 1922, lasting three days, with palpitation and a pulse of 104, which went down to 98 after the third day. In August, 1922, she wrote that she was feeling much better; pulse was 74 to 78, and at night would be 84 or 86, and neck measurement was one fourth inch less. On October 13, 1922, she said she had a fit of indigestion for about a week and felt miserable. On November 9 her pulse was 82 and her weight 120 pounds; she had lost four pounds. Diathermy treatment was given to the liver. On November 23 she felt very well; pulse was 84. On December 7 she was feeling splendid and could do more work about the house; December 21, pulse 80, weight 120.

Since taking the x ray treatments here she said she had improved very much, was stronger, not nearly so nervous, pulse had gone down; liver acted better and she did not have the bilious attacks. Since the diathermy treatment she took only one grain of extract of cascara and one sixteenth grain of podophyllin; she formerly had to take calomel; her skin had a much better color, her appetite was good, she was keeping house, was a good deal more ambitious and did more work.

On January 4, 1923, she had another fit of indigestion, lost half a pound, and pulse was 90. After taking a cathartic pill three times a day with five grains of sodium bicarbonate, she felt much better on January 18th, only taking four doses of the pills; gained half a pound, pulse 88. On February 8th, was not feeling so well; pulse 84 in the morning and at noon 96, at night 100. Restless at night. On February 8th, x ray was administered and one grain of thyroid extract three times a day for a single day; pulse, two or three beats less; no change in physical condition except that she felt rather light headed, and later her pulse was 107 all day. During the next day she took the whole gland pituitary; her pulse was 100 all day. Began to feel better at 9 a. m.; next day after stopping pituitary pulse was 86 and she felt about as well as she ever did. I directed her to take pituitary regularly. On February 15th she took one half grain tablet of pituitary three times a day, every other day. On February 17th she said her pulse was 120 in the morning, she had a slight cold and was having some dental work done, but did not see why her pulse should soar in this manner. I stopped the pituitary for a couple of days and then told her to take it as previously directed. On March 23rd she weighed 124¼ pounds, pulse 84; on the preceding day her pulse was 76 when arising.

To recapitulate, x ray and electrical treatment according to the technic for hypothyroidism brought the pulse down to 84 and diminished the thyroid swelling and the exophthalmos and she became able to do her housework; constipation was relieved. Still, to the trained eye she presented the signs of exophthalmic goitre, and of course the x ray was not a thing which one would choose for indefinite continuance. A test made with the thyroid extract sent the pulse up to 107, and later the reaction to pituitary was found to be favorable. Accordingly, she was placed upon that as an adjunct to having x ray and electricity once in two or three weeks. Inside of two weeks a normal appearance was presented, with slender neck, clear complexion, and a sense of health and strength such as she had not had for years. She is still under treatment.

850 Seventh Avenue.

Reports of Cases II, IV and V will appear in author's reprints.

Modern Methods of Hydrotherapy

By CURRAN POPE, M.D.,
Louisville, Ky.,
Medical Director The Pope Sanatorium, and Consulting Neurologist to St. Anthony's Hospital.

General medical practice is a broad field. If I were placed in the position of having to choose one single modality to meet the exigencies of daily practice in the acute and chronic disorders and diseases of which the human organism is afflicted, I would choose water as my weapon. No single drug, chemical, serum, vaccine, antitoxin possesses such value. No known hygienic or sanitary measure outstrips it. No physical modality can come within striking distance of this wonderful, flexible and powerful remedial measure. Internally and externally, it possesses effective values. It is the most valuable, in my humble opinion, of all physical measures of treatment, being equally useful in acute diseases and chronic states. It can be adapted to almost any ailment and any human being, no matter how strong or how weak. When, as the handmaiden of intelligent medicine, it is discerningly and scientifically applied, its results are more certain than ninety out of every hundred of the therapeutic drugs employed by the practitioner.

In spite of these facts, attested not by a few years of medical practice, but by centuries of accumulated experience and clinical knowledge, the great centres of medical investigations, the foundations, the laboratory workers, pass hydrotherapy by or treat it with the stern contempt and cold disapprobation of the medical stepchild, and refuse or overlook its vast value, and spend hours, days, months and years on the study of some chemical, some serum, some vaccine or microorganism whose field as compared to hydrotherapy is as that of the atom to world cosmos. This is not said to belittle any work of this kind, for every attempt to find any measure or means to combat disease, prevent death, lengthen the span of human life and contribute to that constitutional right, the pursuit of happiness, even though it be an *ignis fatuus*, is to be praised as endeavor whose purpose cannot be but laudable. But why pass by this ancient and glorious therapy, hoary with the accumulated clinical experience of past and present? Why not subject it to the modern laboratory study that its importance demands? Clinical truths and clinical success demand experimental and scientific verification of these facts, under the laboratory scalpel of the cold and cynical worker of today, freed from the enthusiasms of therapeutic success.

The laborer in the vineyard and the worker in the field of hydrotherapy know its value, and know what it will do, but they would like a scientific explanation, cleancut, definite and up to the minute, of the why and wherefore of this wonderful remedy. And its field of usefulness in medicine and therapy is but one phase or facet of its many possibilities. Its daily use is a preventive of disease, a sanitary measure of no small value, and it forms a corollary to athletics of no small importance. Everywhere we turn we find uses for water, from its cleanly and humble use in the culinary department, to its internal use by the direction of the physician. It is indispensable. It is the safest, best and one of the most effective cleansing agents used by moderns to cleanse highways, and byways, the alleys and the streets of cities. It cleanses the air and makes the land fruitful and crops plentiful. Water is cheap. It costs less in municipalities than any other necessity demanded by the growing needs of the people of today. Such a wide sphere of usefulness can be but indifferently covered in a short article and perforce such an article will be filled with the two deadly sins of commission and omission, leaving much to be desired by the reader.

Water is found universally; its temperature range varying from the vapor of steam to its crystalline state—ice—a range of some 150-165° F. It absorbs heat and cold rapidly, and in return rapidly loses its temperature content to the body with which it comes in contact, making it the agent *par excellence* for the application of thermic changes to the external surface of the body. Besides possessing a cleansing, antiseptic action, water by its own weight, when under atmospheric pressure, enables the hydriatrist to produce mechanical effects of varying degree, therapy influencing the peripheral nerve terminations. The ease and rapidity with which this agent may be changed and varied in a precise and certain manner, so that the attendant has under his control within a few seconds of time the temperature, pressure, form of application and duration, render it without question the ideal remedy. It is applicable to any, and all portions of the body with a precision and satisfaction offered by no other agent. Besides the undoubted scientific value of water as a physiological therapeutic agent, may be mentioned its easy accessibility and economy.

The physiological action of hydrotherapy is coextensive with the tissue and functions of the human body. Its responses may be made general or local, according to the extent and location of the application. Results vary according to the method of application, its extent, the duration, temperature, mechanical effects, and such procedures as precede and follow the treatment. Taking a normal or neutral line (94-96° F.), temperature effects are produced as we rise above (warm, 96-98° F.) (hot, 98-104° F.); (very hot 104° F. and above) or fall below (tepid, 92-80° F.; cool 80-65° F.; cold 65-55° F.; very cold, 55-34° F.) this line. The characteristic of the socalled neutral zone is the suppression of thermic stimuli, the cessation of cutaneous impressions, sedation and nerve rest. Above and below this line, the perturbations of the sensory nerve endings are conveyed to the central nervous system, giving rise to myriads of minute impressions, the registration of thermic changes with their resultant effects, viz., general, local, reflex, and transferred. The system rallies to meet the changes, responds to its fullest ability to throw off or counteract their effect, and we then have those wonderful and intricate phenomena known under the general term reaction, much more marked in its response to cold than to heat. The alternate application of heat and cold accentuates the response to each, where the application is made in proper ratio (1).

TEMPERATURE.

Upon the temperature of the normal body, heat may cause a rise from one half to one degree. This is rapidly counteracted in the normal person by the outbursts of perspiration, radiation of heat and heat loss through evaporation. The phenomenon is accompanied by increased vascularity, sensitiveness and reddening of the skin surface, due to dilatation of the bloodvessels. The immersion in a bath moderately warm may elevate temperature by the mere prevention of heat elimination. The primary effect of cold is to produce refrigeration, pallor, and chilliness of the skin surface accompanied by contraction of the capillaries. In the normal individual cold water causes muscular contractions, which produce heat, and if the application is short, the system responds so promptly that no practical reduction in temperature takes place. In febrile states immersion in a cold bath reduces temperature, as Winternitz has shown, when accompanied by sufficient vigorous friction to dilate the peripheral bloodvessels. In many delicate and chronically diseased individuals cold may act as a depressant of temperature unless care is taken to proportion the coldness of the water to the reactive power of the individual. Colder temperatures can be employed with less discomfort where mechanical stimulation is combined; for instance in the douche. Lately Pemberton and Crouter (2) have shown increased alkalinity of the sweat during heating procedures.

CIRCULATION.

Heat temporarily slows heart action, increases the force of the pulse, giving way rapidly to a quickened action of both, accompanied by dilatation of the surface bloodvessels, reddening of the skin, lowering of arterial tension and perspiration. Mechanical stimulation during the application of heat increases the effects reflexly. The internal bloodvessels are contracted reflexly, because the quantity of blood is relatively fixed. Cold is more decisive and rapid in its action than heat. It slows the heart's action, increases the rate of the pulse, and raises arterial tension. The bloodvessels contract, driving the blood from the surface, causing the skin to become pale and slightly shrunken. When reaction takes place the bloodvessels again moderately dilate in what might be described as a tonic state, so that the general vascularity of reaction following the cold application resembles closely the healthy condition of cutaneous circulation. Most of the results of thermic mechanical stimuli upon the bloodvessels are brought about more through reflex action than by any other means, as has been clearly demonstrated by both Schueller and Neumann. It may be noted here that the application of heat, followed by cold, produces a pumplike action beneficial in overcoming congestion or stases in any part of the body.

RESPIRATION.

Heat increases the average number, lessens their depth, diminishes oxygenation and carbon dioxide elimination. Where heat is inhaled, these effects are more rapidly produced. Cold when suddenly applied produces a spasmodic expiration followed by a deep inspiration; when slowly applied there is a great amplitude of the respiration, increased absorption of oxygen and elimination of carbon dioxide in the pulmonary capillaries. After reaction the respiration still remains deeper, there is experienced a sense of relief and fullness of the lungs. The added content of oxygen absorption has a wide influence upon general metabolic processes, especially in the reduction of the complex molecule to the simpler one suitable for elimination. Pemberton, Hendrix and Crouter (3) suggest that the value of heat externally may be due to the heightened output of carbon dioxide.

METABOLISM.

By metabolism we understand all those varied bodily changes that are necessary to the absorption of food, water, oxygen, and other materials, their appropriation by and through the agency of glandular, vascular and tissue action; the conversion of these to tissue use; and finally the reduction of complex waste materials into simpler compounds that elimination may take place, thus maintaining in the normal person a balance. A balanced metabolism evidences an intake and output that is just sufficient and proper to meet all the demands of functional activity, the repair of waste, the furnishing of sufficient force and heat, and the removal of the results of tissue waste. It must not be forgotten that an essential part of this process is the absorption of water from the gastrointestinal tract, and oxygen from the lungs.

The great channel by which pabulum is conveyed to the tissues and the detritus removed from them is the blood, which, as is well known, is the agent so necessary to the reparative process. Metabolism of tissue may be influenced by, 1, activity of function brought about by an increased quantity of blood circulating through the organ or tissue; 2, by change in the composition of the blood; 3, by increased blood pressure causing more blood to pass through the capillary walls and thus favor nutritive changes; 4, by elevating the temperature of the tissues; 5, by influencing the nervous system, especially the vasomotor and trophic nerves, which regulate the capacity of the tissues for absorbing nutriment. The effect of heat and cold upon metabolism is a difference in degree rather than in kind; heat acting less pronouncedly than cold. Heat effects are less likely to be permanent; it enhances the more powerful effects of cold, where it precedes. Cold water has a direct positive and unquestioned influence upon all metabolic activity. Tersely stated, we may say, that under hot and cold water applications we can expect a greater absorption of oxygen and elimination of carbon dioxide and extractives; increased quantity and better character of all bodily glandular juices; destruction of waste materials; the rendering of toxins innocuous; the rejuvenation and cleansing of tissue of such a nature as in a physiological sense, to cause the individual within his tissue to be born again. These results are brought about by the influence above noted through the action largely of the nervous and circulatory system. Pemberton and Crouter (2) have shown that heating the body surface of normal and arthritic persons, tends to produce increased alkalinity of urine, saliva and sweat, but no significant changes in the feces.

MUSCULAR SYSTEM.

Upon muscular tissue of both the striated and nonstriated varieties, hot and cold applications have a decided and rapid action. Heat relaxes normal and overcomes spasmodic states, while at the same time producing an enervation, the result of its general relaxing and atonic action. This is true in so far as tepid, warm and ordinary hot baths are concerned. Very hot baths, such as are constantly employed by the Japanese, and which occidentals stand poorly, have a very stimulating, revivifying and tonic effect resembling in this respect cold applications. Mosse by means of his ergograph and also Vinaj and Maggiora have demonstrated the fact that cold applications in health, as well as in fatigue and pathological states, increase muscular activity fully one third.

These statements apply to the brief application of cold water followed by reaction, for where cold applications are long continued muscular irritability is lessened and lassitude produced. That cold may act in a reflex manner upon the internal viscera is frequently evidenced by the fact that a general cold application, or even an application to the feet alone, may produce evacuation of the bladder. It is a common clinical observation that the application of cold water to the abdominal surface causes contraction and stimulation of the structures of the intestines, and is one of the most satisfactory measures at hand to stimulate secretion and overcome atony and constipation. Upon the muscular structure of the heart cold reflexly influences its action, decreasing its frequency, slowing the pulse and increasing arterial tension. Where used in conjunction with carbonic acid gas, as in the Nauheim baths, it decreases the area of dullness in the dilated and atonic heart, and by the increase of its activity brings about a physical hypertrophy. For these reasons alone hydriatic methods are among the most valuable means of toning the neurotic and muscularly fatigued people of this strenuous age.

BLOOD.

Intake and output may show many variations, but in health the water balance is maintained. No reasonable explanation has been offered to explain the mechanism of this balance. The problem does not seem to lie in the blood changes in tissue; water looms large. Rowntree has described symptoms attributable to water intoxication occurring without significant changes in body temperature, edema or marked increases in plasma volume. They resemble the symptoms of clinical uremia in many respects, and raise the question as to the possible relation of water intoxication, if any exists, to uremia, eclampsia and epilepsy. At any rate, the blood and kidneys no longer deserve sole consideration in the future analysis of the problem of water balance and transport in the organism (7).

Upon the blood its external application is pronounced. Heat stimulates leucocytosis and favors somewhat the elimination through skin and kidney, but as a rule it has little beneficial effect upon the general reconstruction of the blood itself, although where hyperemia is long continued by the action of heat, healing may be induced, but this is not so easily attained by hot water, as by connective heat or radiant energy. Cold, on the contrary, is one of the most valuable means we have of increasing the quantity of hemoglobin and at the same time its oxygen carrying power. As we have heretofore shown the respiration is deepened and larger quantities of oxygen enter the circulating blood. At the same time the cold drives into the circulation the corpuscular elements that have lain dormant in the interstices of tissues and thus adds a quota to the thickness and composition of the blood. Hot applications diminish, cold increases the alkalinity as well as the density or thickness of the blood stream, as has been demonstrated by Strasser. As a natural corollary to the above, we find that normal oxidative process and normal terminal waste materials are better prepared and therefore more quickly eliminated under these influences. Autotoxins, antitoxins, phagocytosis; the reparative and protective influences that lie in the blood cells and plasma are not alone augmented but made more active. With the increased circulation, better distribution of blood takes place, permitting of widespread action under favorable circumstances. Meakins and Davies (4) have shown that external heat increases the percentage of oxygen saturation of the venous blood, while Pemberton and Crowder show that the blood sugar falls slightly. Steuckgold (6) has found that the fibrinogen is increased after cutaneous heat, especially radiant energy.

NERVOUS SYSTEM.

Neutral temperatures (95 to 98° F.) shut out impressions upon the cutaneous surface, and by increasing the retention of water within the skin produces a succulency of nerve endings that result in sedation, a lessened irritability and a lack of stimulation. Heat relaxes the tissues, relieves pain due to spasm and increases the sensitiveness of a part when locally applied. The influence of a lengthened general hot application upon the nervous system is to produce oppression, excitation and a lack of vitality, which may approach prostration.

Cold generally applied and where graded properly to the person is in its action upon the nervous system, above everything else a tonic. Its action is enhanced by mechanical effects and after proper application there is not alone increased physical vigor, but mental as well, which when repeated will result in overcoming nerve exhaustion, irritability, weakness and that long train of psychosomatic symptoms so common in modern civilization. It is to be regretted that the busy, overworked, nerve strained, mentally worried and oppressed persons of this strenuous age do not turn with more frequency to the beneficial and restorative properties of cold water, rather than the brain obtunding, nerve destroying and health dissipating alcohol, drugs and opiates, that simply anesthetize the nervous system rather than remove the products of waste and which, where they are the result of fatigue, may become in turn a cause of disease.

REACTION: CONTRAINDICATIONS.

Following the application of cold the well known therapeutic reaction must be attained, and unless this is secured, save in the case of febrile diseases, the object desired has been defeated and the application robbed of its physiological and beneficial features. Reaction is coextensive with the structures of the human body, every tissue, cell and function feeling its influence so that the individual is strengthened, has a buoyancy and activity both mental and physical to which he has long been a stranger.

Judgment, tact, and a comprehensive knowledge of the particular case reduces the contraindications to a mimimum, but we may say that very hot and very cold baths are as a rule administered with caution in the extremes of life, youth and old age. Delicate persons must be trained and where this is done with care, little risk is entailed. Cardiac, vascular and similar diseases demand caution.

GENERAL THERAPEUTIC ACTION.

I shall only attempt to describe briefly the general therapeutic uses of water as applied to certain groups of diseases, and disorders. Its range is so extensive that it practically embraces the greater part of the domain of general medicine (5):

ACUTE INFECTIONS AND FEBRILE DISTURBANCES.

Typhoid fever, the general type: Free internal water drinking combined with the external use of the cold sponge with friction; the cool full, the tepid full or the neutral full bath all of them to be followed by the cold abdominal compress; the Brand method, the cold full bath at 65° F. for fifteen minutes accompanied by friction. All cool or cold applications must be applied with sufficient friction to develop a cutaneous dilatation of the bloodvessels. It results in a revitalizing of the individual as well as a reduction of temperature.

GASTROINTESTINAL AND HEPATIC DISEASES.

For acute cases general cold sponge for its revitalizing influence; the fomentation (135-160°F) for ten minutes, followed by the ice bag or a cold or stimulating compress to the area affected; may be combined with lavage and colon drainage. For the chronic ones stimulating compress; Neptune's girdle; alternating hot and cold applications; Winternitz's method, the dripping sheet, followed by a cold sitz bath. Probably the best general method is an application of convective heat or radiant energy, followed by the various forms of sprays and douches.

LUNG, PLEURA AND BRONCHIAL TUBES.

Pneumonia, stimulating compress at 60°F. repeated every one to three hours when the patient is awake; may be preceded by a brief fomentation and after the application of compress application, the ice bag may be placed over the cold compress at the places where the infection is greatest. For chronic conditions such as tuberculosis, feeding, fresh air, restricted exercises, combined with radiant energy in the shape of the electric light bath, followed by the various forms of tonic (cold) hydrotherapy; cold sponge, half bath and the various forms of the spray and douche. Watch temperature and reaction.

ACUTE INFECTION (TOXEMIA).

Free water drinking; alkalies and antirheumatics; sweating procedures, especially light and superheated dry hot air, followed by the stimulating compress to the affected joints. Hot full pack, fomentations, and other methods will be found useful. For chronic conditions sweating procedure; hot air, superheated dry hot air or radiant energy, followed by the various forms of sprays and douches, especially the Scottish douche to the various joints affected. Subsequent manipulations are valuable.

ACUTE DISEASES OF THE KIDNEY.

Hot full bath, full dry pack, hot air, superheated dry hot air and electric light baths to the point of profuse perspiration. As a rule cold application contraindicated save when cardiac weakness commences. Then apply the cold compress and ice bag to the precordium. For chronic conditions, moderate or limited water drinking; full wet pack, superheated dry hot air, incandescent electric light bath, followed by the cautious application of cooling measures. Nauheim and full neutral bath valuable.

DISEASES OF THE BLOOD.

Anemia may be taken as a type. General measures that first produce a hyperemia of the skin; hot air, superheated dry hot air, incandescent electric light bath, followed by tonic hydrotherapy among which may be especially mentioned the cold sponge, dripping sheet, half bath and the various forms of the spray and douche.

ACUTE CARDIAC DISEASES.

Moderate water drinking, the frequent application of the cold compress and ice bag over the heart. For chronic type the Nauheim bath associated with the various forms of exercise with which the name of Schott and Oertel are associated. Sprays and douches cautiously.

DISEASES OF THE NERVOUS SYSTEM.

Functional and nutritional diseases of which neurasthenia, psychoneurosis, headache and migraine are types, general measures that produce free elimination, increase circulatory activity and nerve reconstruction. General tonic hydrotherapy of all kinds; ablution, dripping sheet, full wet pack, half bath and various forms of sprays and douches. These may be preceded by any method by means of which heat may be collected upon the surface; hot air baths, incandescent electric light bath and other forms. For the chronic conditions, such as locomotor ataxia, avoid very hot and very cold temperatures; especially valuable are the half bath plain or medicated with friction to the limbs, and the whirlpool bath. As improvement takes place, we may proceed to use the different forms of douches.

MENTAL DISEASES.

Maniacal conditions are best met by full hot, warm or neutral baths, of rather long duration, continuous baths for hours, full wet pack. Where possible to employ it, general tonic therapy has been found signally useful in these cases, as well as in all forms of chronic mental manifestations. All drug, alcoholic, tea, coffee and tobacco habits demand preliminary preparation by sweating procedures until profuse diaphoresis is brought about, followed by tonic methods. During the removal the full warm or full neutral bath, full wet pack, fomentation, cold sponge, dripping sheet and other procedures may be employed. After removal tonic methods until fully reconstructed.

PELVIC DISEASES.

Acute: Hot normal saline douches, vaginal or rectal, every two or three hours, followed by a fomentation or pelvic pack as hot as can be borne. In the interim the ice bag over the inflamed area. This method may be combined with general cold sponge for its tonic effects and hot foot baths for derivative action. Chronic: Build up the general health by every known means using judiciously graduated tonic cold applications, in conjunction with the hot, warm or neutral vaginal douche, hot and cold packs.

SPECIFIC DISEASE AND ITS MANIFESTATIONS.

It will be found that nothing equals hydrotherapy as an adjuvant to arsenic, mercury and potash. Profuse perspiratory methods, followed by tonic hydrotherapy, will enable larger doses to be given or quicker results to be obtained with smaller doses. Nothing equals the incandescent electric light bath, followed by the various forms of sprays and douches.

Diseases of the skin of an inflammatory character and where due to inactivity or torpor of the internal eliminative organs or chronic inflammation of the glandular organs of the body and infections or depressed general health will be promptly benefitted by these methods.

SURGERY.

Hydrotherapy may act as an adjuvant in the upbuilding of the general health of the patient preparatory to an operation. It may act as an alleviant during the active postoperative period, and for the purpose of upbuilding the general health of the patient after the strain of the operation.

It may be stated in conclusion that in acute and chronic disease, no matter where located, we may expect with a reasonable degree of certainty that this method may ameliorate, relieve and often cure, when other methods fail. In chronic diseases of all known therapeutic procedures, it is probably the best single method we have at our command. It is a valuable adjuvant to all other physiotherapeutic methods.

Röntgenoscopy as a Cause of Menstrual Disturbance

By SAMUEL WEISS, M.D., F.A.C.P.,
New York.

Little mention is made in the literature of the dangers of prolonged exposure of the female organs during fluoroscopic examination, and no mention is made of menstrual disturbances as a direct result of these examinations. During the past few years I have come across a number of patients whose menstruation was disturbed after having undergone a complete gastrointestinal examination which included röntgenoscopy and röntgenography. Some of these were patients of mine, while others consulted me after having been x rayed by some one else. In every instance the history was similar. Menstruation was regular up to the examination and had not appeared since, in others it reappeared the following month or later. In still other patients there was spotting only. Two became pregnant who had been unable to become pregnant previously. One patient had severe pain during menstruation due to ovarian trouble; after two months her menstruation reappeared painlessly, and she now says that she is well and that her gastrointestinal condition has improved.

Seeking more light and confirmation, I spoke to a number of röntgenologists who were more than surprised to hear the statements I made, and in one or two instances was fortunate to have the patient present and confirm the facts. Some of these men had not seen the patient again after the examination was over, as they had been sent back to the physician who referred them, and the others did not recall having had complaint regarding menstruation. Further investigation revealed the fact that some röntgenologists do not fluoroscope their patients at all; some do so only during the ingestion of the opaque meal.

This may account for the lack of available data. My patients are given a thorough röntgenoscopic examination commencing with the chest and extending through the gastrointestinal tract. Plates are taken of the urinary system and gallbladder, followed by serial plates in the upright, prone, and oblique postures. The plating and examination are continued for five days or more and are followed by a contrast enema. During the fluoroscopic examination I always caution my assistant not to illuminate the entire field at once so that the patient may not be exposed unnecessarily, but it seems that even this precaution is of no avail in some patients.

Idiosyncrasy may be an important factor, as I have found that amenorrhea occurs more often in the phlegmatic and obese type of females. It may be due to some dysfunction of the glands of internal secretion which become affected through exposure to the rays. Most of these patients present all the phenomena of the menopause, hot flushes, etc. The longest case on record is that of a young lady of twenty-three who has not menstruated for three years, the second is of about eleven months' duration. Both of these patients have gained considerable weight. The others are more recent, as mentioned at the beginning of this paper, and while in several instances the menstruation recurred after the lapse of a month or two, other patients merely spotted.

Some of the gynecologists whom I have interviewed thought that this condition might be due to the destruction of the graafian follicles, while others ascribed it to nervousness and fright during the examination. Whatever the cause, the mischief has occurred and a remedy must be found to prevent it. I have prescribed ovarian, thyroid, and other glandular products without benefit. I have tried dietetic treatment, hot baths, etc., with no result.

In order that these disturbances may not occur in other patients I have perfected a simple device which prevents the rays from penetrating the female organs during röntgenoscopy and röntgenography of the gastrointestinal tract.

Otitis Media and Mastoiditis Treated by Radiant Light and Heat from Electric Lights

By FRANK THOMAS WOODBURY, M.D.,
New York.

It frequently happens in practice, where facilities are limited, that the physician is put to it to improvise substitutes for apparatus which he requires for treatment. The following list of cases, of which the reports are meagre, will illustrate what can be accomplished with makeshifts.

The therapeutic virtues of radiant light and heat are now well known and are based upon physical laws equally well known, so that I shall not enter into their discussion further than to say that the energy of light penetrates the living tissues directly as the wave length, the time of exposure and the wattage of the source, and indirectly as the density of the tissues and the square of the distance from the source. This energy does work by being converted into longer obscure heat waves which are absorbed and carried by contiguity of structure and convection through the blood. This heat has a local effect upon cellular metabolism of the cells themselves and by reason of the heating of the cellular contents and the increased supply of invigorating blood. The increased blood supply is due to the well known vasomotor response to heat. Blood is the only medicine that nature has. No cure is possible without it. I speak of human beings of course. Therefore a supply of good blood being essential, if we can order such a supply we can influence the disease by fortifying the cells which are disabled.

Radiant light and heat is such an agent which we can apply. It is an energy which will do work in the body. The preferred method of applying it is by means of lights with carbon filaments giving off rays from the red end of the spectrum and below it having about five hundred candle power. This is for large skin areas. Local applications and effects may be obtained with fifty candle power lamps. Failing to have either of these at hand the ordinary mazda lamp will serve the purpose.

Case I.—J. L. A., male, single, aged twenty-six years, first seen March 29th. He was complaining of a swollen and running ear on the left side, with a temperature of 102° and a pulse of 132. The ear was discharging freely and the mastoid was swollen and tender. The condition had lasted less than twenty-four hours following a coryza. The patient was put to bed and the usual sanitary treatment of the external auditory canal, nose, and pharynx was instituted and continued at intervals daily. The left ear and mastoid region were irradiated by an ordinary desk lamp with reflector (60 watts, 110 volts) and kept irradiated until April 12th, when the mastoid gave no further evidence of disease. The sanitation of the canal continued until May 2nd when all discharge had ceased. Hearing was 15/20.

Case II.—H. F. N., male, aged nineteen years, first seen January 25th suffering from acute influenza complicated with acute mastoiditis, right side. He also suffered from intense abdominal pains with a boardlike hardness of both recti. As he had had several abdominal operations following appendicitis it was a question whether the symptoms were a part of the influenza or due to adhesions, inasmuch as there was constipation. The mastoid was put under continuous irradiation from a desk lamp and the abdomen was irradiated with six lamps in canopy arrangement. The abdominal pain and rectus spasm were entirely relieved inside of four hours. Mastoid symptoms were relieved by Feb. 4th.

Case III.—S. E., male, aged twenty-one, when first seen on February 4th had an acute suppurative otitis media, with discharge, and acute mastoiditis, both on the right side. The usual sanitation of ear and pharynx was prescribed and a desk lamp applied. In twenty-four hours there was marked improvement in all the subjective symptoms and by February 9th the mastoid was apparently well and the discharge had ceased. The patient was declared well on February 12th. He was then referred to a surgeon who found nothing requiring operative attention in the abdomen.

Case IV.—C. A. C., male, aged eighteen, when first seen on March 5th had a well marked catarrhal bronchitis, a right side suppurative otitis media with discharge, and an acute mastoiditis. Temperature was 104° F. He gave the history of a similar ear condition about three weeks before, which had apparently subsided under local sanitary measures. He also had a markedly sore throat and a general petechial rash over the front and sides of his body which merged into a general rash on the back. A diagnosis of atypical measles was made and the patient put to bed.

The usual attention was paid to the bronchitis and to the throat and nose, and the ears were irradiated with desk lamps. The patient was very septic and partially delirious soon after being put to bed. On March 11th the right elbow became inflamed and swollen. It was also irradiated and later given x radiation for five minutes on three successive occasions with a Coolidge tube, twelve inch distance, no filter, two and a half ma. and four and a half inch spark gap from a portable apparatus. At this date the mastoiditis had cleared up and there was but slight serous discharge from the ear. By March 13th the elbow symptoms had subsided entirely but the patient became progressively worse and died on March 15th. No autopsy was performed.

In all these cases there has been little if any impairment of hearing. The sanitation spoken of was an alcoholic solution of boric acid for the ears and a gargle and nose douche of tincture of iodine, five mils in 250 mils of normal (physiological) saline solution used hot and every hour.

Reports of Cases V, VI and VII will appear in author's reprints.

Editorial Articles

PHYSIOTHERAPY

The word physiotherapy is one of those high sounding forms of speech that cause the average person, professional or lay, to conjure up some mysterious medical means known only to the initiated. As a matter of fact we all use physiotherapy to a greater or lesser (usually lesser) extent. In putting a patient to bed we employ physical means of therapy of the greatest importance, for we change the mechanics of the circulation. In applying a surgical dressing we use physical treatment.

External applications of heat have long been employed in the form of hot water bags or poultices of various kinds. In this connection it is interesting and significant that the heat of the living body was formerly believed to be of an entirely different nature from that which emanated from any nonliving source. A puppy dog was considered a more effective therapeutic agent than a hot water bag, and the heat from a young human body was sometimes prescribed for the treatment of the elderly invalid.

Massage and both passive and active motions have been used more or less from time immemorial, as has also hydrotherapy. The morning cold plunge, which has been recommended for every ailment to which flesh is heir, is but a simple form of physiotherapy. Electricity, in some form or other, has had its vogue, as have sunlight and colored lights.

There have been elaborations in the applications of posture, movements, rubbing, heat, baths, electricity, and light, but after all there is little that is new, and because they do not savor so much of the occult as does chemiotherapy, if we may use the term for drug treatment, they have been neglected sadly by the profession, which has preferred to wield the prescription pen or the carving knife, to the neglect of means which are less mysterious and spectacular. As a consequence, practitioners with neither knowledge nor skill have been reaping a harvest by the hit or miss application of physical means. As we have said in these pages before, it is high time the profession was awakening to the importance of such therapy.

We have heard much more of physiotherapy since the war, in connection with injuries, and, indeed, its importation in this connection was one of the good things which we gained from the war. For a quarter of a century these means had been highly developed in Europe on account of the monetary importance of returning an injured workman to his job at the earliest possible date. The shortening of convalescence reduced the workman's compensation accordingly. When the war came the same machinery was ready prepared for application for the speedy return of the wounded man to his place in the ranks. There was nothing new about it except to American eyes. Since the war one hospital in this country, which deals to a large extent with the wounded from the ranks of labor and which has established an elaborate physiotherapy department, finds that, in its fracture cases, the saving in time of recovery, compared with their records under the older methods, is from ten to thirty per cent., according to the nature of the injury, while the recovery is, also, more complete.

But physical means are as useful in medical cases as in surgical, and even where they accomplish little directly, from a physical point of view, the very fact that *something is being done for the patient* produces an effect mindwards which reacts for speedy improvement or cure.

HEALTH AND LIGHT

The relationship between health and light is becoming more and more generally recognized as time progresses. Of course, the sun is known to be the source of life, but what is beginning to be known is the wonderful curative powers exercised by the rays of the sun, or rather, perhaps, the remarkable range of these powers.

While the warmth of the sun exerts a beneficial influence on vegetable and animal life, more importance is attached by medical science to the increasing intensity of its light, perhaps to the ultraviolet rays in particular. It has been known for considerably more than one hundred years that the green leaf is enabled to absorb carbonic acid from the air, not by the agency of the sun's heat, but by means of the sun's light. This may be termed the chemistry of the spring as applied to the vegetable kingdom. But the animal world, including man, responds to spring, and it is now believed that there is a chemistry of spring in the human body.

Experiments in this direction are said to have been proceeding for some time in Columbia University and at the Home for Hebrew Infants in New York. It is rumored that there has been discovered in the human body a chemistry of spring. Up to the present time these investigations have been pursued only in the case of infants. So far as they are concerned it seems to have been proved that there is an ebb and flow of the chemical contents of the blood. The long winter, with its comparative lack of sunshine and light, depletes the phosphorus content of the blood so that in March this content is at its lowest. From that time it rises steadily up to July, when it begins to ebb again. It is also said that relative darkness has a similar effect on the calcium content of the blood in infants. This explains why daily exposure to sunlight or to the rays of the arc lamp will increase the quantity of phosphorus in the blood of an infant with rickets. Consequently, it would appear that rickets is not a deficiency disease, in the sense that it is due to a vitamine deficiency, or even entirely to a dietetic deficiency, but that a lack of light is as much, if not more responsible, for the condition than a want of certain elements in the diet.

It has been emphasized on several occasions, in the editorial pages of this journal, that rickets does not seem to be a disease of either diet or of insufficient light, but is rather the result of both these causes. It is difficult to estimate which bulks most largely. Recent evidence points somewhat to lack of light. The effect of sunlight in certain diseases of children, tuberculosis for instance, is astonishingly good and from this fact a moral may be drawn, namely, that it is criminal to rear children under the conditions prevailing in many cities. In some sections of down town New York the streets are like mountain canyons into which the sun never penetrates properly. Other streets densely populated, with overcrowded tenements in the lower East Side, are darkened by the elevated railways. Now that our conceptions of the paramount value of sunlight have been widened and deepened, such things should not be allowed to exist. Children who suffer most severely, often permanently, from want of sunlight, should not be denied their right of benefiting from its rays. The sun is life and the boy or girl who does not have a fair share of sunlight is robbed of the greatest gift to which human flesh is heir.

TRAUMATIC RUPTURE OF THE INTESTINE.

When a man has been kicked in the abdomen and continues to feel pain, he should be kept under close observation until all danger that he has suffered a rupture of the intestines has passed, even if he does not seem to be acutely ill. No one can read A. L. Lockwood's study of 652 cases of traumatic rupture of the intestines in the *Canadian Medical Association Journal* for May, 1923, without being impressed with the importance of this dictum. The extent of injury to the abdominal wall furnishes no indication of the amount of damage to the viscera, and symptoms of rupture may not appear for fifteen, twenty, or even more hours, particularly when the intestines happen to be empty when they are ruptured. Although shock develops at once in most patients, it may not occur at all, may develop later, may clear up quickly, or may pass on to secondary shock, even when the rupture of the intestine is complete. In quite a large percentage of the cases the early symptoms are so slight that both surgeon and patient are lulled into a false sense of security until peritonitis excites alarming symptoms and operative measures are undertaken too late.

The small bowel is ruptured much more frequently than the large, in the proportion of nine to one. After complete rupture of the small bowel the mucous membrane usually everts through the aperture and tends to prevent leakage, while peristalsis is inhibited for about six hours. The best chance of a recovery is given by an operation performed within these six hours, for it is practically certain that a patient who has a complete rupture of the intestine will die unless he is operated upon quickly. Delay is fraught with danger when the few, but characteristic, symptoms of rupture are present. Delay until the abdomen is distended and the liver dullness absent deprives the patient of his only hope of recovery, for last resort surgery is useless in these cases. That is why immediate surgical intervention should be urged in any doubtful case, even though the operation may be purely exploratory.

MEDICINE AND THE HUMANITIES

This title Dr. Charles L. Dana, orator at the recent memorial meeting for the late Dr. Weir Mitchell in Philadelphia, gave to his address, published in a late issue of *Annals of Medical History*, and a valuable contribution to medical theory and practice. Dr. Dana is peculiarly well fitted to discuss this subject. He mentions some of the fields of Mitchell's scientific and practical achievements in medicine, then adds: "But in particular he showed the value of the personal equation, in applying our art in practice . . . he was the father of the best modern phases of psychotherapy and in particular he showed how much the nontechnical side of the physician and his cultured values have power to accomplish."

Dr. Dana deplores the tendency of the whole of modern medical education to enlarge and emphasize the technic and to ignore the human side. We are shy of culture today, perhaps because it has been spelled with a K. A person with culture has enough knowledge of the art and learning of present and past times to have what is called a background. "Weir Mitchell, without ever losing his laboratory habits or scientific methods of thought, could not only acquire, but also contribute cultural interests to all those with whom he came in contact." Something can be put into medical education, besides technical studies, which will promote efficiency, usefulness, and happiness throughout a doctor's whole career. A person with this sort of culture will be likely to have mental balance and sanity in his beliefs and ideals. Because of a lack of this background we in America are preyed upon by a succession of wasteful emotions; "a real, serious, simple, cultural training of our adolescents would clear the subconsciousness of irrigating complexes and the activities of desire much more than introspective studies of a morbid personal past. . . . I would go back to nature or to the classical past, rather than to infantile memories." Of course there must come some selfrestraint, and some serious and perhaps dull hours of work, together with certain inhibitions and repressions and some uncongenial concentration; for education would not exist if there had been no enforced guidance of the developing mind. "Surely no one has to have more inhibitions cheerfully sustained than a successful medical personality."

Dr. Dana believes the science of medicine has received its chief impetus from the great classical periods of culture and civilization. He reviews some of the great nations of the world and their contributions to medicine. The Chinese, never having got outside of themselves, and born chiefly to become ancestors, added nothing to medicine. The same thing is true of the other ancient civilizations which were racial and specialized in scope. But the Greeks attained to two peaks in medical progress: the Hellenic, at the time of Hippocrates, and the Alexandrian, when anatomy was studied and dissections were made. In Rome, when culture was at its height under the five good emperors, Galen appeared and lifted medicine to so high a plane that he practically isolated himself, his science, and his art; medicine remained there for about a thousand years.

After the dark but fecundating Middle Ages, medicine was born again in the anatomical work of Vesalius and the surgery of Paré, Paracelsus rediscovered Galen, Servetus found the circulatory system, Eustachius made an anatomy, Fabricius at Padua was teaching Harvey, and Linacre was lecturing at Oxford. But it was not until the nineteenth century that medicine really arrived, and that there was a medical science as well as an art; and this in the Victorian age, so frequently classified, from the cultural point of view, as mediocre, but in which at least humanism and the humanities were definitely pervasive.

Leaving the historical aspect of the subject, Dr. Dana closes his paper with a plea for adding to the medical curriculum such kinds of avocational study as help to make the doctor more human—"studies which make him love his patient more than the disease, and to realize that patients like being caressed rather than being diagnosed. This is forgotten—therefore we have the chiropractors." To have a cultural background means a wise development and training of our higher faculties, and through these such control that we can adjust ourselves to the conditions of life, or change them by our own activities, thus making environment adjust itself to us.

CLIMATE AND CHARACTER.

To say that climate exerts a great influence on the formation or deterioration of character, is to repeat a truism. But exactly why a tropical climate should have such a demoralizing effect upon the character and mental characteristics that it does is not known exactly. Dr. Leonard Williams, lecturing recently at the Royal Institution, London, on the physical and physiological foundations of character, endeavored to solve some of these vexed questions. He explained the inability of the white man to adapt himself to the colored man's country. It is known that this is largely a matter of skin pigmentation. The function of the pigment in the colored races is to intercept the active rays, thus the deleterious effect of the solar spectrum at a certain angle on human beings is counteracted by the pigment. In India, for instance, the inhabitants show a varying degree of pigment, and accompanying this difference is a marked difference in character and characteristics. As pigment varies with climate, so does character vary.

Dr. Williams defined character as conduct so frequently repeated as to become automatic. Different climates determine a different type of people. Those who inhabit a country where the mountains run down to the sea are superstitious, imaginative, and realize how infinitesimal any man is in the ultimate scheme of things. Mountain people are short and so are their animals, as may be seen in the Shetland, Devon, and Welsh ponies.

But to return to the matter of pigment, the lecturer suggested that the pigmentary adaptation to climate is very costly in the matter of energy. That the copious deposit of cutaneous pigment in the dark skinned races is responsible for a considerable expenditure of nervous energy and helps to explain their characteristic lethargy. In short, that the energy expended in the development of color is so considerable as to deprive other parts of the organization of its fair share of that energy and that those parts which are almost certainly nervous parts, are unable to develop beyond the merest animal needs of continued existence. He argued that the energy thus diverted in case of the dark skinned individual, and the darker the skin the less the energy, in the case of the fair skinned person is available for other purposes. Therefore, in the opinion of Dr. Williams it is not difficult to understand the white man's superiority over his darker brother and the ability to develop his nervous system in a degree impossible to his dusky fellow; but he pays a high price in tropical diseases in respect to his fair skin. On the other hand, the energy expended on the skin in pigment protects against disease peculiar to the tropics. On this account, Dr. Williams somewhat distrusts the wisdom of Kipling's advice to take up the white man's burden. Or rather, he thinks that he did not fully understand the almost intolerable weight of that burden. Stated bluntly, the conclusion to which we are driven by this consideration is that the white man is not by nature adapted, and therefore is unable by art, to adapt himself to the colored man's country.

Climate is the reason why the British are great colonizers. Their white skin, according to Dr. Williams's theory, has given them reserves of energy which has lured them to the farthest ends of the world, where, by service and sacrifice, they hope to establish themselves and their British civilization. But their service and sacrifice are destined to ultimate defeat by the very economic forces, which, owing to their ignorance of them, they have failed to recognize. Their white skin is at once their glory and their undoing. They confer on them nervous systems that make them commanders, but at the same time, give them a handicap that they can never overcome. As the writer of "At the Periphery" in the *Medical Press and Circular,* May 9th, last aptly puts it, "Nature has not placed a black man in Australia and a red man in America, just for the fun of the thing." In the course of many generations the British inhabitants of Canada and the British dominions will have deviated so far from the British type as to appear to belong to a different race. In this country it is well known that a few generations have sufficed to modify profoundly the British immigrants. Also it has often been remarked that Americans, whose ancestors have lived in the country for generations, seem to have reverted to or taken on many characteristics of the American Indian, such as high cheek bones, hairless faces, dark, smooth, straight hair and so on.

There is one effect of the climate of this country worthy of analysis and comment which Dr. Williams adduced as an example of profound modification, namely, that after three or four generations white women become sterile. This is a question of extreme interest and importance and a statement perhaps which he did not intend to apply to a vast country in which there are great variations of climate. Possibly some of our readers may like to discuss this point.

Again, the question of the loss of hair is another point of intense interest in man's evolution. At the present time man is the only completely naked animal and in the earlier stages of his existence was protected by a hairy covering. How then did he come to lose his hair? While this problem has not been solved the writer of "At the Periphery" brings forward the ingenious suggestion that the loss of the hairy coat of man took place while the evolving human was inhabiting a warm part of the world. He goes on to point out that *pari passu* with this loss one would expect an increasing pigmentation of the skin to have occurred, of course, extreme hairlessness and extreme pigmentation of the skin are among the main physical characteristics of the negro.

Man adapts himself to climate or climate compels adaptation and influences the human being, physically and mentally. Civilized man is influenced also by the environment, irrespective of climate, mentally and physically, although climate is the most potent factor in this direction. Dr. Leonard Williams's lectures were suggestive, stimulating and fascinating and the hypothesis as to the cause of climate controlling character through the cutaneous pigmentation is worthy of close consideration. Anything which leads one to exercise the reasoning powers outside the dull routine of money making or the not too clean game of politics should be encouraged. It is healthy mental exertion, although it may not bring material gain, fame or notoriety.

THE MOSQUITO AND MALARIA

The discovery of the relationship between the mosquito and malaria is perhaps the most important medical discovery ever made. Malaria has been in the past and is at the present time the most widely disseminated and most prevalent malady of the world, and while there are diseases more quickly fatal there is none that produces greater deterioration in a race or works more lasting harm than malaria. In any country in which malaria gains a hold, there is a progressive deterioration of its people. Malaria is said to be the true cause of the decadence of ancient Greece, and there is little doubt that if not the only cause it was a potent factor in the downfall of the most cultured nation of all time, with the possible exception of the Egyptian dynasty. However, the prevalence of malaria and the injury wrought by it are too well known to medical readers to need emphasis or elaboration, and the statement that the discovery of the connection between malaria and the mosquito is the most important medical discovery ever made is not an exaggeration. It consequently follows that the man who made this discovery is one of the greatest benefactors of the human race.

Interest in the subject of malaria has been aroused recently by the publication of the memoirs of Sir Ronald Ross, the discoverer of the tie which linked the mosquito with malaria, the man who solved the problem. The story of how he brought this about is fascinating and is indeed a romance of science. Ross was the discoverer in so far as in the face of innumerable difficulties he worked out the problem to a successful issue. Laveran, the French Army surgeon stationed in Algeria in 1878, actually discovered and described accurately the malarial parasite as it appeared in the human blood. Golgi continued Laveran's work and Manson suggested to Ross that mosquitoes carried malaria as they did filaria, and Ross proved that Manson's idea was absolutely correct. Full justice was rendered to Ross. When the Nobel Prize was presented to him, Professor Mörner, the rector of the Caroline Institute said: "By your discoveries you have revealed the mysteries of malaria. You have enriched science with facts of great biological interest and of the very greatest medical importance. You have founded the work of preventing malaria, this veritable scourge of many countries."

The solution of the malaria problem led the way to the discovery of the relationship between the mosquito and yellow fever made by the American, Reed, and incidentally these two discoveries applied by Colonel Gorgas rendered possible the construction of the Panama Canal and have robbed the tropics of some of their terror.

INCREASING MORTALITY FROM DIABETES.

The recent greatly increased interest in diabetes, due to the discovery and use of insulin, makes timely the recognition of the fact that mortality from this disease has increased considerably for fully twenty years. Since 1919 the rise has been continuous.

The Census Bureau has recently published some interesting figures showing striking geographical differences in the mortality rate resulting from diabetes. Tennessee has the lowest rate for the white population—a little over six in one hundred thousand of population. New York shows the highest—nearly twenty-two in one hundred thousand. New Jersey, Pennsylvania and Massachusetts also show very high rates, while the southern and western states as a whole show low figures.

These geographical differences are in accord with medical findings concerning the disease. It is well known that white persons are much more susceptible to diabetes than colored persons. This fact accounts for the higher death rate in the northern and eastern States than in the southern. It is also known that susceptibility to the disease varies greatly among the several white nationalities. The Jews and the Irish seem especially susceptible to the disease, and the population of New York and New Jersey contain large number of these two stocks. Also, the diabetes death rate rises rapidly with advancing age, so localities where there is a large proportion of old people will give a high rate. This probably accounts for the high death rates from the disease in Maine, New Hampshire and Vermont, where there are more old people than in many of the other States. Another well known fact is that there is a much higher incidence of the disease among women than among men.

MEDICINE IN THE DEPARTMENT OF PUBLIC WELFARE.

The *Weekly Bulletin* of the Department of Health, of the city of New York, publishes in a recent number a summary of medical progress in the Department of Public Welfare as recorded in the latest annual report. It may be of interest to give a brief review of this summary.

During the year, 46,812 persons were admitted to the hospitals. Treatment of these patients involved 10,268 operations. In addition to these cases, 25,128 wards of the city were given treatment in private hospitals. In private child caring institutions on December 31st, there were 15,837 normal children; the number of subnormal children in the department's charge was 1,381.

One of the policies established during the year, which has already shown excellent results, is the holding of regular conferences of the attending physicians at all the hospitals under the jurisdiction of the department. Here the physical and medical histories of patients are carefully gone over, and treatment and results are discussed. To facilitate these discussions, it became necessary to establish a practical and uniform system of case histories, so competent persons were assigned to take charge of these records at all the hospitals, and specialists were appointed to supervise at the central office the whole collection and coordination of medical and surgical statistics.

A uniform system of nomenclature has been established as an accessory to the proper preparation of statistics and records such as those mentioned above. An active campaign has been inaugurated to call attention to the advantages and opportunities offered by the four schools of nursing maintained by the department.

◆

News Items.

Health Day Celebration.—June 13th was Health Day at the city's jubilee exposition at the Grand Central Palace. Dr. F. J. Monaghan, health commissioner, was one of the official hosts.

Dr. Banting Listed for Annuity for Discovery of Insulin.—Dr. F. G. Banting, of Toronto, discoverer of the insulin treatment for diabetes, was listed for an annuity of $7,500 in supplementary estimates announced in the House of Commons by the Minister of Finance. Premier Mackenzie King has announced that he intends to move in the House for recognition by Parliament of the work of Dr. Banting, to permit the scientist to devote his life to medical research. The Canadian Medical Association at Montreal passed a resolution of thanks to Dr. T. C. Banting, for the discovery of insulin. The Ontario Government has also done so.

Sanitarians Meet.—The twenty-second annual conference of sanitary officers and public health nurses with delegates of the State Department of Health was held at Saratoga Springs on June 26th, 27th and 28th. Many distinguished physicians and sanitarians were present.

Graduate Course at Denver.—A graduate course in ophthalmology and otolaryngology will be given at Denver, Colo., from July 16 to 28, 1923, under the auspices of the Ernst Fuchs Society, the Colorado Ophthalmological Society, and the Colorado Otolaryngological Society.

Will Reopen Hospital.—The former Veterans' Bureau hospital at Dwight, Ill., which has been the centre of a long controversy, will be reopened at once and will be used for the treatment of the milder neuropsychiatric cases. The director said the institution probably would be purchased by the government.

Patient Exposed to X Ray Fifty-six Hours.—The longest experiment on record in the treatment of cancer by x ray was completed in Bellevue Hospital by Dr. I. Seth Hirsch. The patient was exposed for fifty-six hours to an x ray of 250,000 volts. Dr. Hirsch said that several weeks would be required before he could determine whether the experiment was succssful.

Dr. Bowman C. Crowell Elected.—The dean of the Jefferson Medical College announces the election of Dr. Bowman C. Crowell, of Charleston, S. C., as professor of pathology in the Jefferson Medical College, to succeed to the position formerly occupied by Dr. William M. L. Coplin, at one time director of public health and charities of the city of Philadelphia, who resigned from his college position a year ago.

Announcement.—The *Journal of Medical Research* announces that owing to the death of Dr. H. C. Ernst it has now become the property of the American Association of Pathologists and Bacteriologists. The journal will be published in the future by a board of editors appointed by the council of the association. It will be devoted to the prompt publication of original observations and investigations in the field of pathology.

Insulin Fund.—A contribution of $150,000 to fifteen hospitals in the United States and Canada to promote the use of insulin in the treatment of diabetes is the gift of John D. Rockefeller, Jr. Presbyterian Hospital, New York, is the largest beneficiary, receiving $15,000. Thirteen other hospitals get $10,000 each, and $5,000 is contributed to the University of Toronto Banting-Best Fund. The list of hospitals was selected by a committee under the chairmanship of Dr. Simon Flexner, of the Rockefeller Institute.

Honorary Degrees Conferred.—Amherst College conferred the degree of Doctor of Science on Dr. John B. Walker, professor of surgery at Columbia University, and on Dr. James Ewing, professor of pathology at Cornell University.

Yale University conferred the degree of Doctor of Science on Dr. Walter Bradford Cannon, professor of physiology at Harvard; Dr. Jacques Loeb, head of the department of experimental biolody of the Rockefeller Institute for Medical Research; and Henry Fairfield Osborn, of the American Museum of Natural History.

Dr. Woodman to Head Upstate Hospital.—Dr. Robert C. Woodman has been nominated by the State Hospital Commission to be superintendent of the Middletown State Hospital as successor to Dr. M. C. Ashley. Dr. Woodman has been first assistant physician of the hospital for years.

Negro Staff Chosen for Soldier Hospital.—A complete negro personnel will man the Veterans' Bureau Hospital at Tuskegee, Ala. The question of whether negro physicians should make up the staff of the institution, which will receive negro patients, has been the subject of controversy. There was strong feeling among the Tuskegee white citizens against such a plan but according to reports the staff appointments have almost been completed.

Dr. W. J. Mayo Sails for Honors Abroad.—Dr. W. J. Mayo, head of the Mayo Clinic at Rochester, Minn., sailed for Europe to receive degrees and other honors which have been awarded to him by universities in recognition of the work he has done for humanity by his skill in surgery. Dr. Mayo arrived in New York from Montreal, where the Doctor of Laws degree was conferred on him by McGill University. He will go to Dublin, where the Master of Surgery degree will be conferred upon him by Trinity College, University of Dublin. At Leeds, England, he will receive the degree of Doctor of Science from the University of Leeds.

Stage Folk to Have Hospital.—A hospital for the exclusive use of the people of the stage, including the spoken drama, vaudeville and motion pictures is to be built by the New York Theatrical Hospital Association. The association was organized recently. Every branch of the stage profession or industry was represented and Dr. McCall Anderson, 55 West Fifty-fifth Street, was elected chairman of the executive committee. The medical staff consists of Dr. Joseph A. Blake, Dr. McCall Anderson, Dr. Evan Evans, Dr. Walter E. Lambert, Dr. Joseph C. Taylor, Dr. William Brown Doherty, Dr. H. Steers Holland, Dr. Charles Gilmore Kerley, Dr. Floyd McDaniel, Dr. W. Broaddus Pritchard, Dr. Andrew Robinson, Dr. Royal Whitman, and Dr. A. J. Walscheid.

New Officers for Association for Relief of Needy Physicians.—The Association for the Relief of Needy Physicians of Central and Eastern Europe announces its new officers as follows: Honorary president, Professor William H. Welch, president, Johns Hopkins University; honorary vice-presidents, Professor Harvey Cushing, of Boston; Dr. Albert Ochsner, of Chicago, and Dr. Willy Meyer, of New York; president, Dr. Max Einhorn; treasurer, Dr. Henry C. Steneck, and secretary, Dr. Walter F. Bopp. The central committee is composed of the following members: Clifford V. Brokaw, Dr. Harlow Brooks, Dr. Warren Coleman, Max Binswanger, Dr. Wolff Freudenthal, Dr. Jacob Kaufmann, Dr. Fredrick W. Knowles, Dr. William H. Luckett, David Mackenzie, Dr. Robert T. Morris, Fairfield Osborn, Dr. Willy Meyer, Mrs. William Decatur Parsons, Prof. Franz Boas, George Foster Peabody, Mrs. Alvin Scheuer, Mrs. Max Einhorn, Dr. Norbert Stadtmuller, Dr. William H. Stewart, David B. Simpson, Dr. Gregory Stragnell, Dr. Franz Torek, Oswald Garrison Villard, Hugo Volkening, Dr. Ernst Danziger, and Gustav Vintchger.

BERMUDA AS A SUMMER RESORT FOR PHYSICIANS AND THEIR PATIENTS

By E. C. Wilkinson, M. D.,
Hamilton, Bermuda.

The physician who has longed for a glimpse of the tropics has been keenly aware of the fact that during the winter months, his patients, alas, grant him no vacation. And in the summer the tropics have been unthinkable as a vacation resort, because of the burning glare of the midsummer tropical sun.

There is always an answer to the hardest problem, in the back of the book or somewhere. I think that the solution of this summer problem of the physician is geographical and geological, and that it is Bermuda. Here is a group of about 365 islands, situated roughly 600 miles from the nearest land, which is South Carolina, 660 miles from New York, 700 from Halifax, and 700 from the Bahamas, a unique country resting on the top of an extinct volcano and built above sea level only by the work of billions of coral insects throughout countless ages. We are just forty-eight hours from New York, by steamship, and in summer Bermuda is more comfortable than New York, and usually much cooler. Bermuda is really semitropical, because it lies well north of the tropic of Cancer—yet in scenic charm it is, to create a paradox, more tropical than the tropics.

Here, then, is a unique combination, a land situated in the middle of the Western Atlantic, in the coolest imaginable summer setting, yet enjoying a luxuriant wealth of tropical vegetation, exotic flowers, and all the beauties of landscape and sea that one associates with countries and islands much farther south. One of the many riddles of Bermuda is that it looks as if it had been picked up out of the Caribbean Sea, from which, however, it is separated by over a thousand miles of the Gulf Stream.

It is so far north that the average temperature in summer is only 77 degrees. The climate is equable, ranging even in July and August between the narrow limits of three degrees. This may not seem cooler than New York, but in reality it is, because it is never intensely hot in Bermuda. On the mainland there are many days when those twin villains, General Humidity and Old Sol, conspire to produce an intolerably hot and humid condition. This never happens in Bermuda, because its mid-Atlantic location ensures a cooling breeze throughout every day, all day long and all night too. Cool nights, and days swept by ocean breezes may sound too good to be true, but they are the invariable rule in Bermuda.

For physicians and their patients, who seek rest, Bermuda is a haven of quiet, undisturbed by noise. Here are no automobiles, motorcycles, railroads, street cars or factories. And of course no dust or dirt, really the cleanest possible place as well as the quietest. This is a splendid place for nerve cases, but is not recommended for patients with pulmonary complaints, because for some reason it affects them unfavorably. In my own practice I have had many cases which were almost unbelievably helped by the change from the city life to the quiet environment of Bermuda.

It pleases me, as an old resident of Bermuda, to note the increasing numbers of physicians who are visiting our little country every summer. The physician is of course interested largely in the climate and other characteristics of any country which have a bearing upon its suitability as a resort for his patients, but he is a human being himself and when he goes away for rest and recreation he wants to know something about sports, scenic attraction, and the like. So, after a paragraph or two about climate and diet, I shall talk quite frankly about the nonmedical charms of Bermuda.

There is something about the air in Bermuda, during the summer, that invigorates and revivifies. The doctor who sends to Bermuda a patient who is on a diet may find his rules ignored, because the climate has a demoralizing influence upon the appetite, it must be confessed. The most determined dieter eventually yields to the lure of five o'clock tea, with cinnamon toast and marmalade. The fresh vegetables, particularly the famed Bermuda potatoes and onions, will prove palatable to patients who have been told to abjure or limit meats and other proteins.

There is some difference of opinion among physicians regarding the therapeutic value of alcohol. Patients whose cases seem to demand a ration of alcohol may be sent Bermuda safely, because we are a British colony and here the Eighteenth Amendment does not apply.

Restful and soothing to tired eyes, are the miles and miles of tropical flowers in full bloom. During the summer season the rare Bermudian flowers are in their greatest abundance and most colorful bloom. Every roadway and path is bordered with blossoms —gorgeous banks and hedges of oleanders, hibiscus, poinciana, and bougainvillea, set against a background of countless hills covered with juniper trees, and adorning tiny islands set, like jewels, in a multicolored sea.

Even the water takes to itself more colors than Joseph's coat, and changes its hues, chameleonlike, with every passing influence of cloud and zephyr. Due to the coral formations, this crystal clear water reflects many tints of green, blue, cream and brown, blending in tones that suggest opal, turquoise, and topaz.

Other delights for the observing eye of the physician, are the natural marvels, including the crystal caves with their beautiful stalactites, stalagmites, and quasihuman formation; the sea gardens of coral vegetation, inhabited by fish of fascinating hues and form, and the natural arches, cathedral rocks, "devil's hole," and numerous similar phenomena.

The up and doing visitor will find in Bermuda every opportunity for every outdoor sport and the best of the indoor ones. Every day throughout the year, we can enjoy surf bathing in the cleanest, clearest water, and there is excellent still water bathing for those who prefer it. Sailing, canoeing and fishing—296 varieties of fish, by the way. Tennis on turf and concrete courts, and golf on eighteen hole courses with the best of club facilities, available to guests of the hotels. Tournaments are held frequently, and prominent golf and tennis players participate. Cycling, driving, and riding on white coral roads. Sightseeing along pink and white beaches, over sand dunes, in rambling lanes, from the towers of stately lighthouses, in seventeenth century estates, and among the British forts that sweep all of the Bermudas from their lofty heights.

And now for the details of how to get to Bermuda and what the trip should cost. Well appointed steamships of ample tonnage sail twice a week during the summer travel season. The sea is usually mild in summer, and dancing on the deck is a popular diversion. The two day voyage is not too long. There are low cost, inclusive tours, which provide steamship transportation, hotel accommodations and meals, and all desired sightseeing trips. These tours range from eight days to nineteen or more, and the complete cost starts as low as eighty-three dollars for eight days, based on the minimum round trip steamship rate of fifty dollars.

The doctor with a hobby, who likes to learn even while on a vacation, will find in Bermuda a rare hunting ground, a fertile field for studying history, geology, botany, zoology, biology, and even ethnology. Apart from the wealth of natural data available for first hand study, the libraries and societies have excellent records and exhibits, which have been collected for hundreds of years. The bibliography of Bermuda is extensive and varied, and the physician with an inquiring mind will, I believe, find rare delight in it.

Foreign Correspondence.

LATIN AMERICA LETTER.

(*From our own correspondent*).

Balboa Heights, *May* 31, 1923.

TREATMENT OF LEPROSY AT THE PALO SECO COLONY.

Colonel H. C. Fisher, M. C., U. S. A., the chief health officer of the Panama Canal, in his annual report for the calendar year 1922, gives some interesting data on the results obtained in the treatment of leprosy at the Palo Seco Leper Colony. This work was conducted under the immediate direction of Dr. Philip Horwitz, three days in each week being allotted to specific medication. On one day intramuscular injection of the ethyl esters of chaulmoogric acid was given to practically every inmate, the exceptions being those who, by reason of extreme age or physical condition, were unable to take the treatment. On the two other treatment days, the intravenous method was used in about twenty-five per cent. of the cases, in addition to the intramuscular injections. A few were given intravenous injections only. Both methods were founds to possess distinct merits. The intramuscular injections are slowly absorbed over an extended period and subject the patients to the continuous effect of the drug, while the intravenous injections are rapidly absorbed, thus bringing large doses in contact with active areas, but being just as rapidly eliminated, they must be frequently repeated to be of value. The combined method has proved most effective. For all ages from ten years, five c. c. was found to be a practical dose by either route, although in the weak and the young smaller initial doses were given. Larger doses were administered to a few patients, the dose being increased to forty-eight c. c. weekly, divided into twenty c. c. in one intramuscular injection and fourteen c. c. in two intravenous treatments. These larger doses could be tolerated for short periods only and the method was abandoned. Owing to the extreme hypersusceptibility of leprous patients to potassium iodide, which causes dormant lesions to light up and the causative organism to reappear in the nasal discharges, this drug was administered in ascending doses up to a maximum of twenty-four gms. daily, to test candidates for parole.

On the whole the treatment with the ethyl esters proved of value in arresting the progress of the disease and in ameliorating it. This was particularly true when the combined intravenous and intramuscular method of injection was employed. On January 1, 1922, there were seventy-eight patients in the institution and during the year there were eleven admissions. Of these eighty-nine, seven died and five were paroled. Four of the paroled patients had the nervous type of the disease and one the tubercular. Of the eleven admissions, eight were new patients and three were readmissions. Two of the latter were patients who absconded in 1919 and one was a voluntary readmission. This was a patient who had been paroled during the year.

YELLOW FEVER AT BUCARAMANGA, COLOMBIA.

The presence of an epidemic of unknown origin at Bucaramanga, Colombia (a mining centre about one hundred miles inland from Puerto Wilches on the Madelena River and about five hundred miles from Barranquilla) caused considerable apprehension lest it really be an outbreak of yellow fever. In order that an authoritative diagnosis may be made, Dr. Joseph H. White, of the International Health Board, recently proceeded to Bucaramanga in company with Dr. O. L. Pothier, of New Orleans, La., and Dr. Wenceslao Pareja, of Guayaquil, Ecudaor. The party met at Cristobal Colon whence it voyaged to Puerto Colombia. The remainder of the journey was made by train to Barranquilla, thence to Puerto Wilches by river boat and to Bucaramanga on horses. The expedition carried with it an adequate supply of sera and apparatus for the making of the laboratory diagnosis of yellow fever, icterohemorrhagic fever, and malaria. On May 24th an authoritative diagnosis of yellow fever was received and the chief quarantine officer, Dr. W. C. Rucker, of the United States Public Health Service, put in force the quarantine restrictions necessary to the protection of the Canal Zone. It is rumored that the disease exists at Catuca, a town about eighty kilometres north of Bucaramanga, near the Venezuelan border. For the present the origin of the epidemic must be regarded as a mystery but it is expected that the report of the White commission will definitely settle the matter.

SANITARY INSPECTION OF SEAPORTS.

At the request of the Surgeon General of the United States Public Health Service, Dr. W. C. Rucker, the Chief Quarantine Officer, was detailed by the Governor of the Panama Canal to make an inspection of certain ports in Honduras, Guatemala and British Honduras. Dr. Rucker departed May 3rd and returned May 20th after having made sanitary inspections at Tela and Puerto Cortes, Honduras, Barrios, Guatemala and Belize, British Honduras.

Book Reviews

HELIOTHERAPY

Heliotherapy. By A. Rollier, M.D. London: Henry Frowde and Hodder & Stoughton, 1923.

The appearance of an authoritative work on heliotherapy will be welcomed by physicians who seek to marshal all the resources of medical science in their fight against disease. This book by Rollier is an exposition of the methods of treatment which have given such remarkable results in his hands in the treatment of surgical tuberculosis. It represents the fruits of twenty years' experience at his institutions at Leysin. The interesting section dealing with the scientific basis of heliotherapy is written by Dr. Rosselet, a physicist and physician. Special chapters are devoted to the radiographic control of the treatment and to radiotherapy. Although the exact technic described cannot be applied in all climates without modification, the general principles which are so clearly delineated will serve as an adequate guide to treatment everywhere. The importance of careful dosage of sunlight, as well as of individualization, are emphasized. His method consists in exposing first the feet and then the legs and then the arms before exposing the trunk and thorax, beginning with ten to fifteen minutes three times a day. Gradually the time and amount of exposure is increased until the patient graduates to the full sun bath.

The book is illustrated with many case histories. These would be more valuable if they were fewer in number and reported in greater detail. Of 2,167 cases treated during the past eight years, 1,746 are reported as healed. A careful perusal of this publication will be of profit as well as of great interest to every physician.

ROENTGENOTHERAPY IN INTERNAL DISEASES.

Die Röntgenbehandlung innerer Krankheiten. Bearbeitet von Prof. Dr. Bacmeister, Prof. Dr. P. Cermak, Privatdozent Dr. F. M. Groedel, Dr. Lossen, Dr. F. Herzog, Dr. H. Holfelder, Dr. H. Langer, Dr. E. A. Mai, Prof. Dr. P. Morawitz, Dr. Chr. Müller, Prof. Dr. G. A. Rost, Dr. Ph. Keller, Dr. F. Salzmann, Prof. Dr. W. Stepp, Dr. O. Strauss, Dr. Fr. Voltz, und E. Pfeiffer. Herausgegeben von Fritz Salzmann. Mit 55 Textabbildungen. München: J. F. Lehmann's Verlag, 1923, p. 380.

The advance in the treatment of internal diseases with x rays is now great enough to include the unusual amount of material and reports on the subject scattered throughout the literature in one book, so as to obviate a search for this material in the various publications. This book presents the physical and biological fundamental principles of röntgenotherapy as now known in a concise and critical manner. It is intended to aid the physician and student in acquiring a working knowledge of this branch of medicine. The internal therapeutic measures, as well as the indications for surgical intervention, are also discussed in connection with röntgenotherapy. The various subjects are treated by specialists in their respective branches. The chapter on the legal responsibilities of the röntgenologist are discussed by an attorney at law.

After discussing the physical and biological fundamental principles of röntgenotherapy, the röntgenotherapeutic treatment of the following diseases is discussed: pulmonary tuberculosis, glandular and peritoneal tuberculosis, tuberculosis of the supporting tissue, nontuberculous diseases of the bones and joints, bronchial asthma, diseases of the heart and bloodvessels, Basedow's disease, hypophyseal tumors, diseases of the thymus and of the pancreas, endocrine disturbances of the ovary, the irradiation treatment of malignant tumors, and diseases of the blood and nervous system. Special chapters deal with the measuring doses of x rays, the selection of the field of irradiation and röntgen injuries.

TUBERCULOSIS.

Environment and Resistance in Tuberculosis. By Allen K. Krause, A.M., M.D. Baltimore, Md.: Williams & Wilkins Co., 1923.

Rest and Other Things. By Allen K. Krause, A.M., M.D. Baltimore, Md.: Williams & Wilkins Co., 1923.

These two small volumes by Dr. Krause are collections of papers that have been previously published in various journals. Some of the articles have been amplified. The essays cover a number of topics that are of general interest in connection with tuberculosis. Some of the subjects discussed are rest, sputum infection in childhood, adult tuberculosis from childhood infection and its prevention, some problems of medical education in tuberculosis, environment and resistance.

It was a happy thought to assemble these essays into small convenient volumes that would make them easily accessible to the educated public, both lay and professional. The combination of a charming, readable style with scientific accuracy is sufficiently unusual to warrant special mention.

The books will be read not alone with the respect that Dr. Krause's position as a leading authority on tuberculosis naturally commands, but with the keen interest that his fluent and effective presentation will arouse.

THE HEART

A Key to the Electrocardiogram. By Louis Faugères Bishop, M.A., M.D., Sc.D., F.A.C.P. New York: William Wood Company, 1923.

This booklet aspires to present in simple form the rudiments of electrocardiography. The author endeavors to disarm possible criticism by recalling that Huxley said that he had frequently been accused of a lack of technical knowledge of his subject when he had attempted to present it in very simple terms. But Huxley, aside from being a master of style, gave constant evidence even in his addresses to lay audiences of "that enthusiasm for truth, that fanaticism of veracity," of which he spoke in his Aberdeen lecture. Dr. Bishop, at times, sacrifices accuracy in his attempt to present his subject in an elementary manner—indeed, he frankly says, "Any attempting to study the subject beginning with the complete study of physiology is doomed to failure with the average man." The statement that "many hundreds of patients are relieved every year through the knowledge of their condition which is obtained by means of the electrocardiograph" will be questioned by most competent internists. The assertion that "it has made many *previously* fatal disorders of the heart perfectly clear" is certainly untrue in its implications.

There is little point in enumerating the many inaccuracies and half truths in the text. The statement that the R wave represents the isometric contraction of the ventricles, and the T wave the isotonic contraction, will not find general acceptance, any more than that extrasystoles are most often found in cases of long standing myocarditis and should be considered as indications of underlying cardiac damage. The chapter on alternation is particularly unsatisfactory. Dr. Bishop holds alternation to be of little importance, apparently because it cannot be diagnosed electrocardiographically. Aborization block and bundle branch block are confused and several figures supposedly illustrative of bundle branch block, e. g., Fig. 30, give no evidence of this lesion. The book is well printed and bound.

TOBACCO

Tobacco and Mental Efficiency. By M. V. O'Shea. New York: The Macmillan Company, 1923.

The book reviews a mass of testimony upon a question which at the end must of necessity be left open. It is not for that reason without interest and value. The writer has utilized the material gathered from literature and from living subjects. He has brought to light certain facts in the effect of tobacco upon intellectual effort. These results are, however, so uncertain and the given testimony is of so contradictory a nature that little is gained in that direction. The writer has given due reference to the many intervening factors which make the testimony vary thus. Those he has mentioned lie, however, almost entirely in the domain of easily recognized differences of sentiment. They go part way in making of the book an even more valuable treatise on psychology than on the nature and extent of the effect of tobacco. Were these factors pursued below the surface, where wish tendencies and the complexes they build influence both opinion and effect of usage as regards tobacco, still more would be known of unconscious psychology. It is a question whether more than a few salient facts in regard to the properties of tobacco would remain as important factors upon that side of the situation.

THE PROPER ADMINISTRATION OF ANESTHETICS

Practical Anesthetics for the Student and General Practitioner. By Charles F. Hadfield, M.B.E., M.A., M.D. Camb. New York: William Wood & Co., 1923.

In presenting this interesting work on anesthetics the author makes no claim to originality, but aims to present the subject to the medical and dental student in such a manner as to give him sufficient practical and theoretical information to enable him to administer anesthetics for all usual operations in surgery and dentistry. The fact that the administration of anesthetics depends principally on practice rather than on theory, is justly emphasized. Nevertheless, the author has gone quite carefully into a detailed study of the main principles involved in a proper understanding of the subject of anesthetics, without at the same time diminishing the practical character of the work.

The reader of this little volume will be impressed with the aim of the author to concentrate upon the small details that are so important in the proper administration of anesthetics. It is in the carrying out of these details that success lies, in this field perhaps more than in any other. The American reader will find himself face to face with English trade names for masks and anesthetizing apparatus of various kinds, but he will find sufficient merit in the written text to obviate any discomfort on the score of unfamiliarity with these names. The volume is one that can be read with profit by every student who hopes to administer anesthetics some day, as well as by the practitioner who realizes the desirability of refreshing his knowledge of the subject.

WHAT TO EAT AND WHY

What to Eat in Health and Disease. By Benjamin Harrow, Ph.D. New York: E. P. Dutton & Co., 1923.

The author has succeeded in producing a work that safely can be used as a guide for those who want to know what to eat and why. He has incorporated in his work the more important facts which have become established and theories which have been advanced within recent years. Being nontechnical both in character and in style, the laity can readily adopt its teachings, if so inclined.

The book is remarkably free from fads and hobbies, and seems to the reviewer to present the subject of food in a healthy, safe and sane fashion, something which cannot be said of most books of a similar kind. The author advocates a balanced ration, does not decry the use of meat, advocates the use of more milk and less meat, and generally presents a food platform upon which any rational human being can stand and still look with pleasurable anticipation towards meal time.

SURGERY.

Kurzfiefasste Chirurgische Operationslehre (Operationskurs) für Studierende und Arzte. Von Dr. Ad. Oberst und Dr. H. F. O. Haberland. Zweite gänzlich umgearbeitete Auflage mit 254 zum Teil farbigen Abbildungen. Berlin: Verlag von S. Karger, 1922. Pp. vii-228.

This book is intended as a guide to an operative course on the cadaver. It emphasizes the proper handling of instruments, the various incisions of the soft parts and bones and some of the important practical operations. The student must, naturally, have a sufficient knowledge of the topographical anatomy and be able to recognize the indications for any type of operation. The book does not cover the entire field of general surgery, as it discusses only the following procedures: the incision and suturing of tissues, hemostasis, ligations of arteries in the different parts of the body, vascular surgery, amputations and disarticulations, resections of joints, operations on the head and face, the neck, thorax and trunk, the abdominal cavity and the urogenital system. On the whole, this book is incomplete, as it does not contain any of the more recent surgical developments: it includes much that is old and little that is new and, therefore adds nothing to the vast literature on the subject already published.

WEIL'S DISEASE

Ueber die pathologische Anatomie der Spirochaetosis Ictero-Haemorrhagica Inada (Weilsche Krankheit). Von Prof. Dr. Renjiro Kaneko, a. o. Prof. der I. med. Klinik der Kyushu Imperial-Universität zu Fukuoka. Mit sechs mehrfarbigen und zwei einfarbigen Tafeln. Wien, Leipzig, München: Rikola Verlag, 1922. Pp. 181.

The discovery of the Spirochæte icterohæmorrhagiæ as the excitant of Weil's disease led to the further study of its cause, pathology, pathological anatomy, symptomatology, therapy, etc. Since this study great advances have been made, particularly in the pathological anatomy of this disease. The author's work on Weil's disease in Japan is now published in German to make this knowledge available to the rest of the world. It includes a short historical review of the literature up to the time of the discovery of the true etiological factor, the author's own investigations and his pathologicoanatomical findings in the various tissues and organs of the body, and a critical review of the literature which has appeared since the discovery of the true cause of Weil's disease and of that which has appeared since the author's first report on the pathological anatomy. A number of histories, with necropsy and microscopic findings, are also included. An extensive bibliography is appended. Most of the work was done during the period of the World War.

A GUIDE TO THE PROPER USE OF DRUGS

Arzneitherapie des praktischen Arztes. Ein klinischer Leitfaden. Von Prof. Dr. med. C. Bachem in Bonn. Dritte vermehrte und verbesserte Auflage. Berlin und Wien: Urban und Schwarzenberg, 1923. Pp. viii, 288.

This book was written for the purpose of being neither a textbook on materia medica nor a pocket handbook of prescriptions, but rather as a guide for the practising physician in the proper use of drugs and other remedies. It contains hundreds of sample prescriptions instead of theoretical discussions on the action of therapeutic measures. In response to a demand by many physicians for a treatise on the newer proprietary preparations, a number of these have been included. The volume also contains descriptions and uses of the various artificial foods, the treatment of the different intoxications and poisonings, remedies for the various parasites and for special diseases, dose tables, the contents of various drugs sold in packages (proprietaries), tables of the most important baths and springs and a therapeutic register.

ST. DUNSTAN'S

War Blindness at St. Dunstan's. By Sir Arnold Lawson, K.B.E., M.D., F.R.C.S., L.R.C.P. London: Henry Frowde and Hodder & Stoughton, 1922. Pp. vii, 148.

In this little war book the author presents the work done at St. Dunstan's as a technical record of blindness among the British armies during the World War. A great many histories of cases are cited and even though the cases were not completely worked up anamnesically and pathologically, owing to the stress of the times, nevertheless certain lessons and conclusions can be drawn from them. An analytical record of wounds or diseases that resulted in loss of vision in 825 cases is presented. The cases are grouped as traumatic and nontraumatic. The former include those due to through and through penetrating wounds of the orbits, fractures of the skull, concussion blindness without direct wound or penetration of the globe, and miscellaneous cases. The latter group were classified as those caused by inflammatory diseases of the eye (interstitial keratitis and other inflammations) and optic nerve blindness, including primary optic nerve degeneration and secondary optic nerve degeneration following swelling, detachment of the retina other than those of traumatic origin and miscellaneous cases (mostly groups of disease blindness). Disability pensions and the reeducation of the blinded soldier are discussed extensively.

PSYCHOLOGY OF CRIME

The Psychology of the Criminal. By M. Hamblin Smith, M.A., M.D. London, New York: Robert M. McBride and Company, 1923.

Smith speaks with the authority of experience and with an ability to view sanely and soundly the application of the individual psychology of the day to pressing criminological problems. Out of justice to him the word criminological is out of place in commenting upon his book since he avoids terms which encourage the formalized attitudes which have confused and concealed the actual problems in the lives of delinquents. To him these individuals are so much like all other people that in order to explain the special difficulties which their conduct brings to them and to society actual individual research is needed into the determinism of their lives. Here he finds psychoanalysis of invaluable assistance. He gives due consideration to the methods of a psychology of consciousness, especially that developed in mental tests. These, as he shows, if wisely used, precede the deeper investigation. For only in a knowledge of the unconscious of the delinquent such as psychoanalysis gives can his conduct be understood and his adaptation to society be put on its proper basis. The act for which he is accounted delinquent is but a small part of the personality to be discovered and dealt with according to the hidden determinants found. The book is a presentation of the simple but far reaching facts which such psychology reveals are to be considered in the interests of intelligent and constructive work upon delinquency.

PSYCHOLOGY OF RELIGION IN FICTION.

Peradventure or the Silence of God. By Robert Keable. G. P. Putnam's Sons, New York and London, 1923.

In this latest novel Keable brings his hero to a rending of the veil behind which humanity is fearful of peering. Paul Kestern is made of the stuff that permits no stopping until reality stands forth in clear outlines. When he held the tenets of orthodox faith he adhered to them with a stubborn intensity that augured the sharpness of the conflict by which he was to throw them aside. The phases of doubt through which he passes, the attempts he makes to grasp at some different form of the same thing until he strides forth beyond it, all have a special interest. They reveal the character of the emotional life which either clings tenaciously to that which it already possesses, or in its own defense breaks completely with it. The psychosexual phases through which this youth wins his independence are emphasized here chiefly in the strong attachment to his own sex. There is the glowing heat of his love to God, the reverential loyalty to his own father. There is also the temporary submission to the sway of the too gentle Catholic priest, the unsuccessful attempt to yield to the actual presence of Christ in the Sacrament. Something within himself which he cannot explain saves him from the hidden eroticism particularly of the two latter attachments. Then at last it is the woman who lives in clearminded relation to reality who saves him to a realization of himself, strong, independent. Keable has a power in his writing of driving the mists from the reality both of body and of mind, allowing both to stand forth in their own native strength.

Medicoliterary Notes.

The December, 1922, issue of the *Albany Medical Annals* is a memorial number to Dr. Jesse Montgomery Mosher, whose sudden death last December came as a great loss and shock to the medical profession. The frontispiece of the journal is a portrait of Dr. Mosher and the leading article a biographical sketch of Henry Hun.

* * *

Girth Control is a June publication of Harper Brothers. The author is Henry T. Finck, who explains how surplus avoirdupois may be reduced without too much selfdenial at the dining table.

* * *

The Labrador Unit of the College of Physicians and Surgeons of Columbia University has recently issued a small pamphlet describing the work of the unit's Grenfell Missions at Spotted Islands during the summer of 1922. A special feature is made of child welfare work, with the chief object of increasing the child's resistance to disease, and so lessening the danger of infection. Nutrition classes have been established, lectures are given and literature distributed, and two traveling health units with a doctor and nutrition worker for each, and a dentist in one, are in operation to give illustrated health lectures, examine the children, and make individual recommendations.

* * *

Mary Austin has in the June issue of the *Bookman* an article of unusual interest on Sex in American Literature. One of the chief points made is that the American public has always been and still is remarkably unsophisticated in its sex perceptions, a fact to be traced probably to the influence of Puritanism; and that the recent superfluity of writing and discussion on sex is partly caused by the introduction into our literary life of points of view on this subject contributed by some of our recently acquired members and descendants of European nationalities and races, whose experiences and points of view are quite different from ours along these lines, and, being such, have become objects of interest and speculation to our own young writers and thinkers.

Announcement has recently been made in this country that the degree of Doctor of Medicine and Surgery has been granted to Signorita Andreina Gatti-Casazza, niece of Signor Gatti-Casazza, general manager of the Metropolitan Opera House, by the Royal University of Pavia. It is considered in Italy one of the greatest of honors to receive a degree from this institution, which is almost six centuries old.

The Children's Bureau has recently published a report of conditions in the beet fields of Michigan and Colorado, especially in regard to child labor, which is an indictment of the terrible situation in both States. In Michigan, four fifths of the children are under fourteen, and one fourth under ten. One mother casually stated that her little boy had worked in the fields "ever since he could lift a beet." During the thinning process, children often work from nine to fourteen hours a day. The beet laborers' families live in the beet shacks, which are mere makeshifts for shelter and desperately overcrowded, for five or six months out of each year. Conditions in Colorado are described as practically the same.

A June publication announced by Appleton is entitled *Life and Confessions of a Psychologist;* the author is G. Stanley Hall, and the book is in the nature of an autobiography, including material on the history and development of psychological science during the writer's lifetime.

* * *

A recent bulletin of the Metropolitan Life Insurance Company states that during 1922 the case fatality rate of smallpox, or the number of deaths in one hundred cases, was five times the figure for 1921. Among 9,936 cases reported in 276 cities in the United States and Canada, 495 deaths occurred, or five per cent. of the total cases. In 1921 only one per cent. of the 31,489 cases were fatal. "The decline in the number of cases," says the report, "may be only a casual circumstance. The lesson to be drawn from the records of the year is that smallpox in a virulent, death dealing form has entrenched itself in recent years among American and Canadian populations. . . . The wide acceptance of the false teachings of the antivaccinationists and the indifference of the American population to the continued and vehement warnings of its public health officials have prepared tinder for what may well become a catastrophe of the first order. . . . The press and every other facility for teaching the lesson . . . should support the effort of Federal, State and local officials to protect America from a threatened danger."

The Department of Commerce has announced that provisional birth figures compiled by the Census Bureau for the first six months of 1922 indicate lower birth rates than for the corresponding months in 1921. In the latter year, the rate was 24.8; in 1922 it was 22.7. North Carolina shows the highest, and Vermont the lowest rate. Death rates compiled for the same periods are higher in 1922—12.6 against 12 in 1921.

Practical Therapeutics

X RAY AND COMBINED TREATMENT OF ACNE VULGARIS.

By Joseph Jordan Eller, M.D.,

New York,

Attending Dermatologist, French Hospital; Clinical Assistant, Department of Dermatology and Syphilology, Vanderbilt Clinic, Columbia University.

Permanent care of acne vulgaris is as a rule difficult, inasmuch as recurrences are caused by various factors. The disease must be attacked from different angles and it often taxes the mind of the trained dermatologist to get the desired result. In order to understand the reasons for a combination of treatments, I shall present a brief review of this disease.

Acne is a chronic inflammatory disease of the oil glands, usually of the face, but also of the chest and upper part of the back—characterized by comedones, papules, nodules, pustules, or a combination of any or all of these, and frequently is seen between the ages of twelve and thirty.

The face is the usual site attacked and the severity varies. In some cases only comedones and an oily skin are present; others have papules or indurated pustules; and it may be so severe as to be complicated by small furuncles. The disease most often begins slowly and gradually grows worse, that is, of a more severe type. The acne patients usually have a greasy and relaxed skin and often have associated an oily seborrhea of the scalp as well as of the face. In these cases, the gland outlets are large and comedones are more numerous. Acne, as a rule, lasts for several years and often leaves small pitted scars according to the tendency of the patient's skin to scar formation, which varies in different persons. The socalled clinical varieties of acne are named from the predominant type of lesion present, such as acne papulosa, acne pustulosa, acna indurata, and acne atrophica, according to whether papules, pustules, indurated inflammatory hard papules and pustules, or atrophic pitted scars are present. Most of the lesions, if not all, have their beginning in a blocking up of the gland outlet, but this is not demonstrable in all, especially the deepseated lesions.

ETIOLOGY.

The disease is a common one, and attacks both sexes about equally, usually starting about the time of puberty and often persistently recurring up to the age of thirty, if untreated. Unna, Gilchrist, and Sabouraud described a bacillus called the acne bacillus as being the causative factor in acne vulgaris. Strickler, Kolmer, and Schamberg have not confirmed this finding in their investigations. The evidence today leans towards acne being a germ disease only secondarily. The primary causes are those which bring the skin into a receptive condition for the parasitic invasion, without which the bacteria which are on the skin normally would not become pathogenic. Any one of the following conditions, alone or in combination, contributes to the primary cause of acne: constipation, intestinal fermentation, lack of exercise, circulatory weakness, chlorosis, endocrine dysfunction, menstrual disturbances, systemic intolerance to sugars and starches, and, externally, anything which has a tendency to block the gland openings, although this plays the smallest rôle. Acne is often worse about the time of the menstrual periods. Other patients have a new or a worse outbreak of acne lesions after indulging in sweets or excessive starches.

PATHOLOGY.

Acne is essentially an inflammation of the sebaceous glands with hypertrophy. This is concomitant with a hypersecretion of the glands and a resultant excessive pouring out of oil on the skin, giving the greasy complexion which these patients as a rule have. Secondarily, these glands become infected with the staphylococcus albus and the socalled acne bacillus, causing a more marked inflammatory zone about the glands; in other cases causing small dermic abscesses; and in some, small furuncles, according to the severity of the disease. The greatly enlarged oil gland, the opening of which is plugged by a comedone, causing the gland to become filled with sebum and cell detritus, with an inflammatory zone about the gland, is the characteristic picture of acne.

PROGNOSIS.

Acne recurs at times after the most rigid treatment, if the underlying causes still persist after the patient is cured locally. The patient must work closely with the doctor in following all directions, both before and after cure. If acne is untreated, pitted scars often result, and the disease may last from ten to fifteen years. If treated properly, a permanent cure may be effected in from two to six months, according to the severity and to the general condition of the patient.

TREATMENT.

Both systemic and local treatment are necessary.

Local treatment.—The skin is to be washed thoroughly with a mild soap once or twice daily. No cold creams or greasy creams are to be used, for they aggravate the condition by supplying grease or oil where there already is too much. Only pure unadulterated powders may be used, such as pulverized rice. The patient is instructed to rub a sulphur lotion gently on the acne areas and to apply a coat of the lotion which dries like calcimine. This lotion differs from the white lotion of sulphur in the United States *Pharmacopœia* by being about five times the strength, making it as thick as a thick cream, instead of a milk consistency, which latter is almost useless in acne. The following is the formula for the heavy lotion:

Zinc sulphate	ounces 2
Potassium sulphuret	ounces 1½
Glycerine	drams 1
Rose water	drams 1

While this is being used the x rays are given in fractional doses. The action of the x rays is to contract the greatly enlarged oil glands back to normal size. The sulphur lotion can be used with perfect safety with the x rays when the latter are given in the doses to be described. The acne areas are x rayed weekly with one quarter of an unfiltered skin unit, according to the MacKee standard, for ten doses. If the acne is completely gone, the x ray treatment is stopped, and the patient is told to keep on with the lotion for about eight weeks longer. If the acne is still active, the lotion is continued and the x rays are given through a quarter of a millimetre of aluminium in doses which are equivalent to one eighth of an erythema dose for about six more treatments. If the acne still persists, the x ray treatment is discontinued and other treatment is instituted which will be described later. Most cases of acne are cured permanently with about twelve x ray treatments when combined with the heavy white lotion, plus the systemic therapy. The writer has found in his experience that much more x ray treatment is necessary when acne is treated without the lotion described. No bad effects have been observed in the use of this combination in a large number of cases, so that it is preferable to use it to shorten the course of treatment.

The x rays are given in the following manner: The patient is put in a recumbent position on a table and the eyes, scalp, and neck are covered by lead foil or lead rubber for protection from the x rays. Then one quarter of a skin unit, unfiltered, is given, with the centre of the target directed at right angles to the zygoma, first on one side and then on the other side of the face. In addition, it is preferable, although not always necessary, to give one eighth of a skin unit, unfiltered, with the anode directly over the nose (full face). For this latter dose, the plane of the face should be at right angles to the perpendicular for the lateral exposures. The back and chest, if involved, should receive one quarter of a skin unit, unfiltered, to each half, care being taken to shield the face and scalp from exposure. Occasionally it is necessary to give separate exposures to the external surfaces of the arms. The factors for the unfiltered one quarter unit of x rays are ma. 3; sp. g. 6; t. 30 sec.; d. 8 inches. This dose is equivalent to slightly less than one quarter of an erythema dose, and when given weekly, twelve to fifteen such exposures are easily tolerated. The factors for the filtered treatments, which are usually started after the tenth unfiltered exposure, are ma. 3; sp. g. 6; time 42 seconds; distance 8 inches; filter, one quarter of a millimetre of aluminium. This is equivalent to slightly less than one eighth of an erythema exposure, and four to six such doses can be given quite safely.

All comedones are expressed. At times the sulphur lotion causes a mild irritation of the skin. The patient is then instructed to stop the lotion and to use instead a greaseless cream, such as the vanishing creams on the market, until the skin inflammation subsides. The object should be to effect a complete and permanent cure with as little x ray treatment as is possible, and after a course of treatment consisting of three to four skin units given fractionally in one quarter skin unit doses, the course should not be repeated for at least a year.

Constitutional treatment.—The patient is instructed to leave sugars and starches out of the diet as much as possible. A list is given the patient on which the restricted foods are written, among which are butter, nuts, cheese, ice cream, soda, syrups, beets, bananas, oatmeal, and potatoes. Some patients lose too much weight on this, and in these the diet restriction must be lightened. For constipation, cascara sagrada or a rhubarb and soda mixture, with or without tincture of gentian, is given in the necessary doses. The diet is corrected to avoid fermentation. Anything that might help the patient's general condition is suggested. If there is an endocrine dysfunction, this must be corrected. The menstrual function and genitourinary tract should receive attention. A good formula for the treatment of the oily seborrhea or dandruff of the scalp, which usually is found in the acne patient, is the following:

Euresol	drams 1½
Bichloride of mercury	grains 3
Salicylic acid	drams ½
Glycerine	drams 2
Oil of bay	minims 3
Spirits vini rectif. (70%) q. s. a. d.	ounces 8

This lotion is to be rubbed on the scalp once daily.

In patients where recurrences have occurred in spite of all the treatments and where they have followed all the directions, a combined stock vaccine consisting of the acne bacillus, colon bacillus, and the staphylococcus albus was given in one quarter billion doses every four days, increasing the dose to one billion of each bacterium until forty to fifty doses were given. The cases which have recurred following x ray, lotion treatment, with systemic treatment, comprised about ten per cent., and a large percentage of these relapse cases were permanently cured by giving the vaccine by the method described above. It was found that the vaccine had no effect until a large number of treatments (about forty) were given, and that the only reason for failure here was in the vaccine being given improperly or in too small a number of doses. It should never be given at intervals of less than four to six days and it should not be increased more rapidly than half a million of each bacterium at a time. If the dose is too large, or if the injections are given too frequently, more harm than good may result. A large number of cases of acne are under treatment with the use of the vaccine alone, and the results will be reported later.

Acne often leaves pitted scars which mar the appearance of the skin, and these pitted scars are especially annoying to women. A skin thus scarred may be improved by means of the Kromayer light administered with pressure, the same method being used as in the treatment of port wine marks. The light which is watercooled is placed against the scarred skin and the patient presses it against the affected part. Full power is used (fourth button of rheostat) and the water is allowed to circulate through. The time varies from three to six minutes and a reaction occurs which blisters and peels the skin. With this treatment the scars are less evident and the skin over these areas looks much smoother. Several such exposures may be necessary in a severely scarred case.

Since MacKee's technic was introduced in this country, acne can be treated with the x ray safely, and since we have this agent, the time of cure has been lessened from one to two years to a few months. In conclusion, acne must be treated in great detail from every point of view if a permanent cure is to be expected.

24 WEST FIFTY-NINTH STREET.

Proceedings of Societies

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS

Twelfth Triennial Session, Held in Washington, D. C., May 2, 1922.

Dr. Frank Billings, of Chicago, in the Chair.

The Trend of the Practice of Modern Medicine.—Dr. Frank Billings, of Chicago, in his presidential address said that since the close of the war the mind of the whole world had been occupied with reconstructional ideas on politics, education, industry, and all other human activities. Modern medicine, among other activities, had been greatly influenced by postwar ideas. Gradually, during fifty years of evolution, the practice of medicine had been broadened by the development of chemistry, physiology, pathology, bacteriology, and sanitation, till it had advanced to the stage of an applied science. Medicine, however, would always remain essentially an art, measurable by the technical skill and experience of the physician. The older anatomical conception of disease had given way to the study of functional disorder, that is, the greater emphasis was now placed on pathological physiology.

While specialization had developed considerably before the war, it had been enormously fostered by war conditions. Training camps had been supplied with good diagnostic and hospital facilities and the necessary equipment and personnel, backed by military discipline. The result was that many general practitioners became specialists during the war. This had created a condition of ultrascientific medicine and the development of overspecialization. Group practice and the group clinic had become more and more in evidence.

To estimate the practical value of this group system, it should be asked how many patients really required the benefits of an application of precise methods of diagnosis, as represented by the group clinic and its laboratory, and how many required hospital care. From long hospital and clinical experience, Dr. Billings said that a correct anatomical and functional diagnosis could be made in from eighty to eighty-five per cent. of all patients of an average community by a qualified, industrious, painstaking, general practitioner, by the sole application of the trained mind, the special senses, the hands, and a simple laboratory equipment. Also, eighty per cent. of patients would receive efficient care as ambulatory or house patients. The minority of patients required attention in the specially equipped hospital.

It was unfortunate that derogatory effect on the public and the medical profession had been created by a too great multiplication of clinical laboratories. The special laboratory diagnoses were costly, were often used unnecessarily, and too frequently were made to take the place of a primary, fundamental, physical examination. Equipment for the simpler laboratory tests should be in the physician's office.

In regard to medical education, the standard of training of the medical student in the United States was one justly demanding praise, but it was to be remembered that the teachers were usually specialists, and were apt to emphasize details of a given specialty, rather than to provide training in the broad general principles of pathology, medicine, surgery, and obstetrics. The constituent associations of this congress had a membership which included the foremost medical teachers, research workers, and specialists in the clinical and preclinical branches of medicine, and was therefore fitted to assume the responsibility of leadership in a solution of problems dealing with medical practice and the health and welfare of the public. The influence of the congress should be directed toward efforts to secure a curriculum, having as its purpose the proper education of the general practitioner. This would correct the unfortunate tendency to overspecialization, which had tempted many men who were insufficiently qualified to take up special lines of work. The correction of this would lie in the development of opportunities in various parts of the country for adequate postgraduate training in the several specialties of medicine and surgery.

While no one could appreciate more than he the value of modern medical facilities to the practice of modern medicine his endeavor had been to point out erroneous tendencies which were derogatory to the profession and unjust to the public. It was believed that the past history of the medical profession, characterized by high motives, selfsacrifice and productive service, would enable it voluntarily to correct existing conditions, detrimental alike to medicine and to society.

Factors Which Enter Into an Adequate Diet.—Dr. E. V. McCollom, of Baltimore, discussed the viewpoint of investigators in the field of nutrition, especially in regard to their interpretation of the failures and successes of experimental work. Fifteen years ago it was believed that chemical analysis gave reliable information as to the physiological values of food, that is, if one knew what the diet should contain in the way of proteins, fats, carbohydrates, and mineral salts, a diet could be planned to insure complete physical wellbeing. A number of facts, however, forecast by chemical investigation, had arisen as the result of study. Thus it was found that there was a great variety in the quality of proteins from different sources. There were poor, medium, good and excellent proteins in natural food stuffs, also some of those which were poor when serving as a sole source of nutrition, served greatly to enhance the value of other proteins in the dietary. For instance; proteins of cereal grains, tubers and fleshy roots had no high nutritional value, but became valuable if taken in combination with those of animal tissues.

Another fact well established in the past twelve years was the existence of certain substances, called collectively vitamines, and designated vitamines A, B, C, and possibly a fourth, if verified by further experimental work. The importance of these factors was shown by the fact that there was a specific disease which attended the lack of each specific vitamine. The ophthalmias of dietary origin arose from loss of vitamine A in the dietary. This vitamine was by no means distributed in the natural food stuffs in sufficient abundance to meet physiological requirements of men and animals. Deficiency of vitamine B caused in animals a polyneuritis of dietary origin and in humans beriberi. Scurvy was due to the lack of a specific substance, vitamine C. This latter was the most easily destroyed of the essential food components. There was also a group of nonspecific diseases, in which no single dietary factor could be held responsible, and of these the most prominent and most studied was rickets. Pellagra was also a disease due to nutritional deficiency. In regard to general nutritional studies, a diet selected from cereal grains, legumes, fleshy roots, and muscle cuts of meat (no matter how varied or palatable) would never support adequate nutrition in man or animals. This had been substantiated by experimental data.

There were only three types of diet which had ever succeeded in the nutrition of men and animals; first, a strictly carnivorous diet in which all parts of the animal (muscle, fat, viscera, and bony substances) were eaten; second, the oriental diet, in which a large quantity of leafy vegetables were consumed (unknown in the American dietary); third, a mixed diet, typical more or less of the American dietary. The latter, however, was often seen to contain too large a proportion of food derived from highly milled cereals (rice, white bread, etc.) in addition to muscle cuts of meat, potatoes, sugar, etc. This diet often gave rise to a large number of cases of skeletal defects among children; from twenty to thirty per cent. of school children were underweight for their age. The large prevalence of dental caries was due to lack of elements necessary to the teeth when forming, and, dietary reform was the only means by which better dentition would be obtained.

Experimental Evidence of the Lack of Vitamine B in Nutrition.—Lafayette B. Mendel, of Yale University, said that in the investigations on vitamine B the opportunity to employ animals without the limitations of research on man, had been an important factor. Experimental polyneuritis opened the way for the interpretation of beriberi as an avitaminosis.

Hopkins in 1906 prophesied that the health and nutrition of individuals depended on unsuspected dietary factors. At the present time, thanks to the experimental studies conducted in a number of laboratories, several of these factors had been discovered; although their chemical nature had not yet been identified, the evidence for their need was beyond question. Vitamine B was distributed widely in plants and animals.

When a diet lacking in this factor but considered otherwise adequate was offered to animals, they soon declined to take sufficient food, no matter how palatable it might be. The adjuvant to the diet of this substance rapidly brought a return of appetite. This same phenomenon was observed in convalescents too long maintained on restricted diet, and manifesting an indifference to food.

Human beriberi and the experimental polyneuritis of birds had long been studied. Recently similar experiments had been carried out on the dog. This animal, if maintained for weeks on a diet lacking in vitamine B, first suffered from vomiting and gastric disturbance, and then refused to eat. Later its limbs became involved progressively in spastic paralyses. Convulsions followed and the animal finally died. If vitamine B was administered before the advanced stages, the animal recovered entirely and promptly.

Recent workers, he said, believed that lesions of the gastrointestinal tract were associated with deficiency in this vitamine; and that the functional activity of the lymphoid tissues was interfered with. Lymphopenia and marasmus accompanied withholding the vitamine B, and disappeared with its restoration. In other words, its presence was necessary to the normal functioning of lymphoid tissue. Specific lesions of the lymphoid tissues, however, might be induced by different agencies, of which vitamine deficiency was only one.

Distribution and Properties of Vitamine C.—H. C. Sherman, of Columbia University, said that the lack of a necessary antiscorbutic substance in grains, vitamine C, was established by experiments on guineapigs which were fed entirely on rice or on oats. The instability of this vitamine would make difficult its isolation in pure form, but it was measurable by its effects experimentally, and its occurrence in various food stuffs could be computed. Grain, he said, in a resting state contained little or any of this substance, but properly sprouted grain and cereals showed a marked development of vitamine C. A preexisting substance in the seed becomes transformed into vitamine C as the grain sprouted. This fact was of fundamental significance. Vitamine C was water soluble and passed in the sap into the most actively growing, succulent parts and juicy stems and tubers of plants. Oranges, lemons, tomatoes, and raw cabbage were rich sources of vitamine C.

Animals seemed to depend on plants for their needs of vitamine C. Rats, which were almost immune to scurvy, seemed to require little of it. Animals did not seem to store vitamine C to any extent in their bodies, but possibly the blood contained it, as did milk. The milk of the cow fed on fresh grass in summer was rich in this vitamine. This fact applied also to the milk of the nursing mother, who should receive an ample allowance of fruits and vegetables to supply vitamines B and C, as well as good milk rich in vitamine A. Vitamine C appeared to play a part in the nutrition of animals, even those immune to scurvy, as rats, which did not manifest scurvy, were nevertheless improved in health and vigor by its addition to their diet.

Physically and chemically, vitamine C was soluble in water and alcohol and was destroyed readily by heat or oxidation. Destruction by heat was more rapid in the presence of air. Both time of heating and temperature exerted an influence on the destruction of this vitamine. Thus, the lowest time and temperature of heating must be used to conserve this vitamine in the preservation of antiscorbutic foods. The vitamine appeared more readily destroyed in alkaline solution than in acid. It was abundantly preserved in canned tomatoes.

Relation of Diet to Rickets.—Dr. Paul G. Shipley, of Johns Hopkins Medical School, said that in the Carolinas, in the latter half of the eighteenth century, slave owners experimented with diets affecting the health of slaves, and found that certain dietaries induced dropsy and disease of the eye. It was now known that the deficiency of vitamine A in the diet was followed by such diseases as keratomalacia, xerophthalmia, night blindness, iritis and panophthalmitis. Human beings, however, were not so likely to suffer starvation in regard to one food element, as they were to suffer deficiency.

Rickets was a deficiency disease, the effects of which were seen most in the skeleton, but it also involved the whole organism, including the nervous system. The pathology of the blood in this condition deserved careful attention. The normal calcium content of the blood was from nine to eleven milligrams to one hundred c. c. of blood; the normal phosphates from four to six milligrams to one hundred c. c. of blood. The calcium might not be reduced, the phosphate might be greatly reduced and occasionally the serum calcium was reduced while the phosphate was normal. If the serum calcium fell below five, there was tetany, either latent or manifest. To be effective a diet must restore the normal phosphate level and the normal blood calcium. Disturbance of the calcium phosphate ratio produced rickets, as normal bone growth depended upon this balance in an optimal measure. In cases of rickets with latent tetany, there was marked blood calcium reduction. Codliver oil seemed the most suitable substance to compensate for faulty calcium phosphate balance. Whether this contained a vitamine identical with vitamine A was not known. It might be different.

Another point was the influence of light in the prevention of rickets caused by deficiency diet. Sunlight, the mercury quartz vapor lamp, the cadmium arc, iron chromium arc and ultraviolet light, were all capable of curing rickets in the presence of vitamine deficiency.

Relation of Diet to Pellagra.—Dr. Joseph Goldberger, U. S. Public Health Service, reviewed the more outstanding significant evidence bearing on the relation of diet to pellagra including the essential dietary factor on which the relationship depended. In studying diets known to have been connected with pellagra and comparing them with those of known value in curing and preventing the disease, he had been led to conclude that the etiological factor was a deficiency of protein, best determined by estimating its biological value by means of Thomas's ratings. A liberal intake of minerals and known vitamines failed to prevent the disease, so that, of the dietary essentials known at present, the protein factor alone seemed responsible in the prevention or causation of pellagra. Since protein was now regarded as a complex of aminoacids, varying in different proteins, the etiology of the disease would appear to bear definite relationship to the aminoacid makeup of the protein supply. Just what combinations of aminoacids were primarily concerned remained to be determined. The possibility of an as yet unknown factor, conceivably a vitamine alone, or in combination with the aminoacid factor, was not absolutely excluded.

Application in Practice of the Results of Vitamine Studies.—Dr. L. Emmett Holt, of New York, said that vitamine studies had given a new basis for the evaluation of foods. Many articles, valueless as regards energy, furnished an essential nutritive substance, entirely apart from their chemical constituents. Thus, tomatoes, cabbage, spinach, lettuce, chard, and green vegetables and fruits had an essential food value, although composed chiefly of cellulose, water, acids and salts. The preparation, preservation, and storage of foods, rendered necessary by conditions of modern life, sacrificed a certain amount of their nutritive value, and this was true also in regard to the overrefining of flour and grains. On the other hand, food preservation presented immense advantage. White wheat flour kept for months without deterioration, while whole wheat flour spoiled within thirty days, so that its general adoption was practically an economic impossibility. The sterilization of milk, while it might injure its vitamine properties, ensured protection from milk borne diseases, and the same principle applied to the preservation of vegetables, fruits and eggs.

Infants were likely to be injured by the sterilization of milk by heating, as through this process vitamine C was destroyed, though apparently vitamine A and B were not injured. To counteract this danger, some anticorbutic must be added to the diet of infants reared on sterilized milk. The body had a store of this vitamine which became exhausted after a time and scurvy appeared. As the winter milk of cows was deficient in vitamine content, it was well to add some substance rich in vitamines to a milk diet in winter. The diet of the nursing mother might be affected similarly, which would account for puzzling cases of scurvy developing in breast fed infants. In the Philippines beriberi often developed in the nursing children of rice fed mothers. Malnutrition among poor children was due to lack of vitamines A and C in the mother's diet.

The effects of vitamine deficiency were most clearly noted in times of war, stress, and famine, and were seen in prisons, army camps, on shipboard, and in the arctic regions also in infancy. Vitamines were so widely distributed in natural food stuffs, that unless the diet of children was very onesided, they should receive their full supply in a normal diet.

In vitamine investigation there were two important points; one their specificity, and the other the small amounts necessary to produce effect. Vitamine requirement, however, was affected by other conditions, such as confinement, exposure, hard work, and poor food. There was a growth requirement in children, while adults had a maintenance need only. Infants suffered most from deficiency, as their growth was greatest and their diet most restricted.

The specificity of vitamine was absolute. They were not interchangeable, and seemed entirely independent of each other, each serving a definite nutritional function. There was no proof that benefit could be derived from an excess of them. A practical question was whether a relative deficiency would not produce a general condition of ill health rather than outspoken disease. The only proof of this would be the therapeutic test and decided improvement resultsing from the addition to the diet of substances rich in vitamines.

In conclusion it should be said that for children plenty of milk and a varied diet were indispensable. Skimmed milk should be supplemented by butter.

When milk was excluded, green leafy vegetables should be plentifully used. Whole grain cereals and potatoes furnished water soluble vitamine. Fruits and canned tomatoes furnished antiscorbutic vitamine and cabbage was rich in all vitamines.

Dr. A. F. Hess, of New York, in discussing these papers, said that he was much interested in the work dealing with rickets. Much had been learned by experimental investigation since the rat had been used for laboratory work in this connection. Rickets was a common disorder in the temperate zone, about seventy-five per cent. of breast fed infants showing tendency to it in some form or another. It had a seasonal incidence, being highest in March and April. That might be due to absorption and not entirely to food intake. There was a reciprocal action between light and food, and a seasonal effect on blood phosphate, as shown by examination of the blood month by month. In the summer time the ratio was four to five milligrams to one hundred c. c. of blood, but in January, February, and March, it was much lower. Sunlight had a direct curative effect on rickets, but artificial sunlight was also efficient. The reciprocal action of light and food was a wonderful thing, and had broadened the conception of the pathology and treatment of rickets. Physiologists had long been cognizant of the effect of light upon plants and animals, but had neglected to apply the principle to human growing infants.

Letters to the Editor.

TREATMENT OF ANGINA PECTORIS

PHILADELPHIA, *May* 7, 1923.

To the Editor:

Referring to the interesting and instructive symposium on the heart and bloodvessels in the current issue, let me direct special attention to the following extracts from the contribution by Sir James Barr, since it presents a substantial basis for the study of angina pectoris: "Every muscle in the body is a miniature battery and the efficient discharge of its function depends upon the integrity of the cell and its electrical charge. . . . In health these batteries work well, but in disease there are many breaks in the continuity of the series. So far as we know the presence of free calcium ions in the blood and tissues is necessary for effective muscular contraction. The calcium ions diminish the irritability of the muscle fibre, but increase the force of its contraction." My impression is that angina pectoris is due to calcium depletion, affecting not only the nerve structure responsible for cardiac innervation, but also the protoplasmic cells comprising the muscular tissues of the heart itself; and the basis for this deduction rests upon certain well known and fully recognized conditions in physiological chemistry as follows:

We are advised by physiological chemists that the proportions of calcium and magnesium in the cerebral nerve structures are as one to ten and assuming that this is true of all the nerve structures throughout the body, we can readily calculate the effect of a diminished alkalinity in the blood upon the nerve mechanism as well as upon the musculature of the heart. According to Matthews, the nerve structure is an electrically charged colloid, the colloid particles carrying the positive electrical current, while the liquid portion carries the negative electrical current, and, of course, so long as the body fluids are normal, molecular changes will continue. If a diminished alkalinity of the blood is present, a condition which I have termed acid excess, it follows that there will be calcium depletion, because calcium being a stronger base than magnesium, it will be leached out, and the effect of this is a replacement, substitution or infiltration by magnesium, because nature abhors a vacuum. Under such conditions we have an abnormal state of the nerve supply, magnesium being a nonconductor of electricity, or a poor conductor, the normal transmission of nerve impulses is hindered, arrested or destroyed. Such being the case, the attacks are characterized by great pain and, as has been well outlined by Dr. Alexander Blackhall-Morison in his contribution on The Blood Pressure in Angina Pectoris, there follows an indefinite period of low blood pressure, simply because the normal alkalinity of the blood has not been restored and there is a lack of calcium ions to produce and maintain magnesium dissociation.

Another item is worthy of consideration in this connection, as I have referred to the protoplasmic cells composing the musculature of the heart, because they are also subject to the same or similar conditions as pointed out in the case of the nervous system. For example, the nucleus of the cell has an acid reaction, while the ectoplasm is alkaline, and the physiological chemist will readily understand this peculiar condition favors and promotes interchange between the intercellular and intracellular fluids. If the intercellular fluids carry an excess of acid, this acid will penetrate the alkaline ectoplasm and affect the intracellular activity, and as a result of this disordered condition we have edema, which is merely a symptom of calcium depletion. That leads to the inference that in all cases of angina pectoris we have this fundamental condition to contend with and we can trace that condition to dietary deficiency, not necessarily to the lack of the various vitamines, but to lack of food materials which carry a surplus of calcium or lime. This statement is made with confidence and the claim is advanced that we have here a scientific basis for the administration of calcium.

Naturally, the question will arise as to the most appropriate calcium preparation and this is a matter of no little significance. From current literature I find that physicians readily take up with the administration of calcium chloride, giving it internally as well as intravenously, but my experience does not warrant its administration in this class of cases, for the simple reason that nearly all of these patients (asthmatic and heart disease cases), suffer from dyspepsia characteristic of the typical acid excess, and the administration of the chloride only adds to their misery for the reason that it increases the production of hydrochloric acid. It may be given in the form of the carbonate, provided it is submitted to thorough trituration, but the most conspicuous preparation of calcium is to be found in the colloid, which presents the inert infinitesimal particles—they neutralize acidity and utilize it.

Abstracts from Current Literature

RÖNTGENOTHERAPY

Röntgenotherapy of Peritoneal and Genital Tuberculosis in the Female.—W. Weibel (*Wiener klinische Wochenschrift,* November 30, 1922) reports thirteen deaths in forty-one cases treated with röntgenotherapy. None of the patients died from genital tuberculosis but six died from peritoneal tuberculosis. The results were so good that the author prefers the less dangerous irradiation treatment in every case. It is not necessary to use a powerful apparatus. The author recommends röntgen ray treatment only in the adhesive form of tuberculous peritonitis. Better results were observed in general tuberculosis.

Preliminary Report on the Treatment of Pertussis by the X Ray.—Henry I. Bowditch and Ralph D. Leonard (*Boston Medical and Surgical Journal,* March 8, 1923) report the results of x ray treatment in twenty-six cases of pertussis. The patients were from three months to forty years of age and in different stages of the disease. Each patient received three or four applications of the x rays at intervals of two or three days. The doses were regulated according to the age of the patient and the total amount given any one patient was well under an erythema dose. Seventy per cent. were relieved through a more marked diminution of spasms than would be accounted for by normal convalescence. In a small percentage the spasms and whoops disappeared entirely within six days, and the patients were clinically well, except for possibly a very slight cough. Ten per cent. of failures included one case that was moribund and one rather difficult feeding case. The writers are unable to give any rational explanation of the action through which the x ray appears to produce the beneficial results, but do not believe it is due to any direct bactericidal action. No definite conclusions can yet be drawn, but this form of treatment seems to be more efficacious than any other at present known.

Studies on the Changes Produced by Röntgen Rays in Inflamed and Connective Tissue.—Alexander A. Maximow (*Journal of Experimental Medicine,* March, 1923) induced inflammation in rabbits by introducing flat, rectangular, celloidin blocks with slits, parallel to the surface, cut into the subcutaneous or intramuscular tissue of the abdominal wall. The animals were then rayed. In some instances the raying was done before the introduction of the celloidin blocks. The action of x rays on inflamed tissue manifested itself first by a considerable depression of the usual reaction on the part of the fibroblasts, which undergo a high degree of pathological hypertrophy of protoplasm and nucleus, the latter often showing amitotic constriction instead of mitosis. There is an intensive edema of the connective tissue surrounding the foreign body, and in its immediate neighborhood a thick layer of netlike clotted fibrinous exudate is formed. The leucocytes and polyblasts showed no distinctive qualitative changes. The rate and duration of all the cells coming from the blood were increased at first, and secondly there was a distinct delay in the process of the common transformations usually undergone by the polyblasts on the field of inflammation. There was swelling of the endothelial cells in the bloodvessels, with fragmentation of the nuclei. The striated muscles showed degeneration of the fibres. Maximow states that it is surprising that his results seem not to agree with the predominating views on the action of x rays on cells.

Reliability of the Röntgenological Diagnosis of Duodenal Ulcer.—Martin Haudek (*Wiener klinische Wochenschrift,* December 21, 1922) believes in the reliability of the x rays in diagnosis. He found them to fail only twice in thirty-eight cases. The most important characteristic finding is the indentation or retraction at the greater curvature immediately below the pylorus, then, in the order of their importance, come the hourglass form, and finally the elongation of the pyloric canal. The niche formation, which is so important diagnostically in gastric ulcer, is not so important in duodenal ulcer. The asymmetrical position of the pylorus is also a valuable sign. Furthermore, the lesser density of the shadow (as a result of the admixture of a great amount of duodenal secretion) and the flighty filling of the duodenum in many cases is an indication of the location of the disease.

Röntgen Diagnosis of Intracranial Affections with the Aid of Dandy's Procedure.—Artur Schüller (*Wiener klinische Wochenschrift,* August 24, 1922) states that encephalography (the röntgenography of the skull after the inflation of air by way of the lumbar sac) makes possible, 1, the confirmation of the presence, nature, and extent of a hydrocephalus; 2, the differential diagnosis between cerebral and cerebellar tumors; 3, the differentiation between a local erosion or protrusion of the skull cap which is produced by a local process (as for example a tumor of the hypophysis) or by a diffuse pressure on the brain (hydrocephalus); 4, the localization of a cerebral tumor, at least as to the site of the involvement and occasionally also in regard to the exact diagnosis of the focus, size and nature of the lesion; 5, the confirmation of a craniostenosis combined with hydrocephalus, and 6, the decision as to the possibility and nature of an operative interference.

Röntgen Diagnosis of Gastric Ulcer.—G. Jansson (*Finska Läkaresällskapets Handlingar,* July-August, 1922) emphasizes the great rôle played by radiology in ulcer diagnosis and describes the röntgenological symptoms of ulcus ventriculi. The leading symptom is the socalled ulcer niche which presupposes the crater of the ulcer to be filled with contrasting pulp, and which appears on the röntgenogram as a projecting shadow from the gastric silhouette. Its appearance varies according to whether the ulcer is penetrating or nonpenetrating and callous. The author describes the various niche types and their varying positions, reporting several of his own cases which are illustrated by plates. The indirect symptoms of ulcus ventriculi are then enumerated, the spastic as well as the organic hourglass stomach being mentioned, and also disturbances of locomotion and secretion.

Proper Doses of X Rays in Internal Medicine.—Robert Lenk (*Wiener klinische Wochenschrift,* August 17, 1922) contrasts the medical (processes applied for normal healing) with the surgical x ray technic (producing extirpation and destruction of pathological tissues). The latter technic should be avoided from the viewpoint of the internist, inasmuch as it is in absolute contrast to the principles of internal medicine. Consequently, the following demands should be met: the smallest possible but adequate dose and distributed dispensation under constant control of the subjective and objective finding. These points of view are still so new that the subject is still in its inception.

Deep Therapy.—C. C. Anderson (*British Medical Journal,* July 8, 1922) states that the method of application may be grouped under three headings: 1, röntgen irradiation alone; 2, röntgen therapy with radium irradiation, and 3, röntgen therapy with physical agents to increase the efficacy of the x rays: a, electrolysis with metallic salts, and b, packing the patient in paraffin blocks. Röntgen therapy alone avoids burning the patient, but it is too early to speak of definite results. The combined röntgen and radium therapy promises to give good results. Röntgen therapy with copper electrolysis is proving to be the most satisfactory method of approach. There is a slight danger of burning the bowel, but the results far outweigh this disadvantage and besides, the scar is loose and supple and suppuration in fungating growths is diminished; it is specially effective in malignant skin lesions that are resistant to the other forms of treatment, including radium. It is still too early to judge the results from röntgen therapy and the packing with paraffin blocks, but if it should prove to be efficient, the technic will be greatly simplified.

A carelessly focussed application of intensive rays may be stimulating to distant portions of the growth and this source of danger must be guarded against. The patient should be subjected to extensive clinical, laboratory, and radiological examinations to determine the exact location of the tumor and the fitness of the patient to undergo this form of treatment; a blood examination is most essential for this purpose. The secret of success with deep therapy lies in an intimate cooperation between the clinician, the pathologist, the physicist, and the radiologist.

RADIUM THERAPY.

The Cure of Trachoma With Radium Rays.—L. Müller and F. Högler (*Wiener klinische Wochenschrift,* December 7, 1922) report some excellent results in five cases of trachoma treated by radium. The treatment is simple and absolutely not dangerous when carried out by an experienced radiologist. It is a distinct advance over the methods used heretofore. The authors irradiate three to five times with 150 to 250 milligram-radium element hours for each dose.

Radium Therapy of Cancer.—Arthur Burrows (*British Medical Journal,* July 8, 1922) asserts that the radium treatment of cancer is most complicated: the dose depending largely upon the changes occurring in the tumor as a result of its nature or position. The possibility of actually stimulating an outlying portion of the growth, which is radiated insufficiently, must be borne in mind. Before absolute success with radium therapy is possible, a great many physical measurements of the different parts of the human body and of pathological growths and a complete investigation of the nature of the lethal dose for cancer cells are necessary. This information will give an approximate idea of the proper method of treating tumors in different locations, although even then some insurmountable biological difficulties, such as the resistance of the organism as a whole and of the tissues locally to cancer, will require elucidation.

Even in inoperable cases, the author reports that 7.5 per cent. of all the cancer cases treated with radium the patients are alive and well after periods of two to seven years and that in many cases of carcinoma of the cervix uteri, breast, skin, lip, etc., the patients have been saved from death by radium; endotheliomata of the parotid gland and spindlecelled sarcomata show still more gratifying results. A great many palliative cures, short of absolute cure, have been seen, while in nonmalignant conditions, like exophthalmic goitre, Hodgkin's disease, keloid, cavernous and capillary nevi, the percentage of cures is high. Radium therapy is specific for excessive uterine hemorrhage and spring catarrh.

Radium in Keloids.—E. M. Daland (*Surgery, Gynecology and Obstetrics,* January, 1923) says that it seems probable that every keloid can be destroyed by radium if a sufficient dose is used. Silver filtration (one millimetre) should be used in keloids of recent origin, in children, in people of dark complexion, and in exposed areas, such as the face. The dose should be from thirty to sixty millicurie hours, according to the age of the patients. Practically unfiltered tubes should be used on all other keloids. The dose should be from fifteen to thirty millicurie hours a tube. It should be explained to the patient that ulceration will result from this type of treatment. There is no evidence to show that the destructive doses damage the tissues so that the lesions recur. There is no lessening of the tendency of an individual to develop keloids.

Technic of Intrauterine and Intravaginal Application of Radium.—H. Eymer (*Zentralblatt für Gynäkologie,* July 22, 1922) discusses the principle of the Heidelberg procedure of irradiation for carcinoma of the uterus with radioactive substance with the elongated forms of applicators. The other unusual feature of the procedure is the use of medium large amounts of radioactive substances for single treatments. All of the preparations used are administered with brass filters one mm. thick and accurately fitted. Some of the applicators are tubular and contain about twenty-five mg. radium element, being more or less concentrated according to the length of the tube. One applicator has the shape of a capsule and another that of a hemispherical shell placed over a massive brass hemisphere, which acts as the filter. The latter is especially indicated in crateriform carcinomata. In carcinoma of the cervix, the external os must be found with a sound and when found the canal is dilated with longitudinally perforated Hegar dilators and the uterine cavity is measured. The appropriate applicator is selected according to the size of the cavity, which is then filled with a series of apparatus. If long filters are required they can be screwed together in tandem fashion. In carcinoma of the body of the uterus, the concentrated preparations are placed above and the less concentrated preparations are applied below. Twin filters are applied in a wide uterine cavity. Additional applicators may be applied in the crater and in the vagina for carcinoma of the cervix. The hemispherical or the capsular forms are used, depending upon the structure of the cervical tumor, and a special apparatus is used to hold them in place.

When radiating the vaginal tube, the bladder and rectum must be protected. A distance of at least 0.8 cm. from the external wall of the filter (made of hard rubber and in various shapes and sizes according to the shape and size of the vagina) should be maintained. A modified Zwanck pessary is used where radiation of the parametrial tissues is desired. The duration of the application can be determined only biologically according to the nature of the malignancy. The fact that the propagation of the tumor has probably extended beyond the palpable portion of the tumor must always be borne in mind and the guiding principle should be to arrange the radiation in such a manner that by using every possible form of application the greatest amount of radiation is obtained at the greatest possible distance from the source of radiation, namely by crossfiring. The most practical duration for intrauterine radiation was found to be three times twenty-four hours and for intravaginal radiation twice twenty-four hours, at one sitting so as to avoid the cumulative effect on the connective tissue.

RADIANT LIGHT IN THERAPEUTICS

Bactericidal Action of Ultraviolet Light.—S. Bayne-Jones and J. S. Van Der Lingen (*Bulletin of the Johns Hopkins Hospital,* January, 1923) describe methods by which exact determinations may be made of the wave lengths of light which kill bacteria. They used the sparks of various metals as sources of ultraviolet light; except in a few experiments when it was necessary to take advantage of sunlight because of its greater intensity. In most of the work the quartz spectrograph was used. The absorption spectrum of a bacterial emulsion was correlated with the limits of the bacterial action of light. The effect of temperature and the influence of hydrogen ion concentration upon the limits and velocity of the germicidal action of ultraviolet light were determined. The authors draw the following conclusions from this work: The bactericidal action of light is confined to the ultraviolet region of the spectrum, beginning at 350 u u and extending with increasing intensity to the shortest wave lengths measurable with a quartz spectograph: 185.6 u. These limits coincide with the absorption of ultraviolet light by bacteria. The temperature coefficient for the bactericidal action of light was found to be 1.05 over a range of 10° C., and the constant u in the formula of Arrhenius was 934 to 975. An increase in hydrogen ion concentration of the fluid in which bacteria are suspended during their exposure to ultraviolet light increased the velocity of the bactericidal action. The accelerating effect began at Ph 4.6, the isoelectric point, and was very strong in fluids more acid than this. Neither temperature nor the hydrogen ion concentration rendered bacteria sensitive to the longer wave lengths of light.

A New Protection Against Injuries From Phototherapy.—I. M. Eder and Leopold Freund (*Wiener klinische Wochenschrift,* August 10, 1922) report that æsculin protects the skin. It is obtained from the bark of young horse chestnut trees in the spring, which is a bad time for the decortication of trees. Experiments showed that naphthol sulphuric acid absorbed the short waved portion of the spectrum (up to 350 u u). The alkali salts absorb also the violet. The authors successfully used a two to four per cent. lanolin salve and showed that the word antilux could be distinctly written with the salve on the skin which had been irradiated. The skin area so treated shows a normal hue. The most important element in the treatment is the thorough rubbing in of the salve. No harmful effects were observed. The salve should be rendered insoluble in water (lanolin) so that sweat will not interfere with its action. This preparation can be used as a substitute for the expensive æsculin. It is called antilux.

Quartz Lamp Irradiation in Pemphigus Neonatorum.—Richard Gralka (*Monatsschrift für Kinderheilkunde,* July, 1922) reports partially successful results with the quartz lamp irradiation in four out of five cases, as far as a considerable shortening of the course of the disease is concerned. After three to four irradiations, the danger of autoinfection was overcome. In two cases, in which the life of the children was at least jeopardized, secondary infections were avoided by the prompt healing under the influence of the quartz lamp and the outlook as regards life was considerably improved. Quartz lamp irradiation treatment does not render the usual drug therapy dispensable, but nevertheless it is a valuable adjunct and it should therefore be tried in all prognostically doubtful cases.

Influence of Light in the Prevention and Cure of Rickets.—Alfred F. Hess (*Lancet,* August 19, 1922) asserts that it is impossible to appraise accurately the rôle of light in the incidence of rickets until more is known of the dietetic deficiency or errors in a qualitative sense. Inasmuch as breast feeding does not protect against rickets, diet alone cannot be the dominant etiological factor. Rickets occurs even in babies whose mothers are well nourished and who partake of a liberal and varied diet. The conclusion must be that breast milk, although valuable, is provided with but a scant factor of safety against rickets and that an additional protective influence is needed, namely light. In London and New York, the milk is far more adequate and normal than the supply of light.

Behavior of Germs on the External Skin Toward Ultraviolet Light.—Ludwig Schmidt (*Centralblatt für Bakteriologie, Parasitenkunde u. Infektionskrankheiten,* Heft 4, 1922) concludes that germs lying superficially on the skin are destroyed to a great extent by ultraviolet light in doses which show no injurious secondary effects on the skin itself, but that the more deeply lying germs are protected from the effects of the rays. The sensitization of the skin by the spraying of eosin on it makes no difference. This effect was evidenced on the germs of suppuration, which had already produced a slight inflammation of the skin and also on the germs that are present on the normal skin.

Treatment of Lupus by the Diathermy Condensor Spark.—A. E. Milner (*Lancet,* December 23, 1922) is convinced that this form of treatment does not fail to cure lupus vulgaris simplex and as this is the first stage of the catarrhal form, the importance of treating these cases early is apparent. The ideal patch for treatment is the small one; more extensive patches can be cured, but the treatment is tedious. This treatment is superior to scraping owing to the fact that the diathermy spark actually destroys the tubercle bacillus, whereas curettage leaves behind many tubercle bacilli in the vicinity of the wound. The cases of lupus that persisted were those with tuberculous affection of the mucous membrane either of the nose, gums, or lacrymal apparatus. The latter parts should be examined carefully, as otherwise reinfections are bound to occur. In butterfly lupus of the face, where the nasal mucosa is also affected, the nose should be treated first and cured as much as possible before commencing diathermy treatment of the face.

Observations on the Effect of Artificially Produced Light on the Capillaries of the Skin and Its Evaluation as a Biological Criterion for the Determination of the Dose in Deep Röntgen Therapy.—Gustav Welsch (*Münchener medizinische Wochenschrift,* No. 15, 1922) finds that an observer, who is well versed in the appearance of the capillaries after deep röntgen therapy, will be warned against too excessive a dose by a pronounced pathological test picture of the capillaries and, in its presence, will administer a suberythematous skin dose. This provocative irradiation should last for two minutes. If an apparently macroscopically normal looking skin in a patient who is about to be subjected to deep röntgen therapy shows signs of an excessively marked light reaction, and if this suspicion is strengthened by an examination of the capillaries, presenting an abnormal picture, the skin should be tested with the mercury quartz lamp for twelve minutes; after six hours the skin should again be examined. If the circumscribed; marked hyperemia and exudation of the bloodvessels is observed, the length of the intervals of the röntgen irradiation should be adjusted accordingly; but if the visual field, even after the light provocation, appears poor in circulation, the usual skin erythema dose may be exceeded in deep röntgen therapy.

Diathermy in the Treatment of Diseases of the Bladder in the Female.—Iwan v. Büben (*Zentralblatt für Gynäkologie,* July 15, 1922) asserts that diathermy is a valuable adjunct in therapy, owing to the promotion of the healing power associated with the increased temperature and resulting hyperemia and the other physiological powers, especially in regard to its powers of relieving pain in the painful cystitides and in tenesmus. Diathermy is produced by means of an electric current of high tension and rapid alternation, which produces heat in the deeper tissues. The amount of heat developed depends upon the intensity of the current, the resistance of the perfused tissues, and the size and form of the electrodes. A large and a small electrode are used, the current being made to pass from the larger electrode to the smaller one, so that most of the current and heat are developed at the latter. If the electrode is too small, a coagulation of the tissues results with the use of strong currents; this is called a cold cautery and is used with good results for the extirpation of bladder tumors, chiefly papillomata.

The author treated with diathermy fifty cases, chiefly of cystitis, with incontinence and painful urination. The treatment may be extravesical or intravesical. The extravesical treatment is given with olive electrodes (with a thermometer embodied in the instrument) applied intravaginally; the external electrode, consisting of a lead plate as large as the palm of the hand, is applied over the bladder at the symphysis. The results with this form of treatment are not as good as those obtained with the intravesical form. For this form of application, the author devised an irrigating electrode, through which the bladder is first filled with one hundred to three hundred c. c. of physiological saline solution and the electric current is then applied in the same manner as in the extravesical treatment. This treatment is given three times weekly for ten to twenty minutes, with a current of 0.5 to 1.0 ampere. Marked improvement in the symptoms is noticed after ten treatments. The best results are obtained in the cases of painful urination and in enuresis nocturna. Diathermy is contraindicated in every form of inflammation associated with a rise of temperature. It is especially indicated where all other forms of treatment are of no avail.

Additional Indications for Quartz Lamp Irradiation. — Hans Reh (*Strahlentherapie,* 1922) showed that in diseases of the joint capsule, ligaments, adjacent muscles and tendons, both the acute and more chronic diseases were cured without exception in a very short time without recurrences. In diseases of the synovia, which have not as yet produced any considerable hindrance to the smooth joint action and therefore could have produced only slight changes in the articular surface, the disease was cured by several irradiations, but recurrences were seen unless about eight irradiations were administered. In cases with advanced destruction of the smooth surfaces, as in the joint, the effect from treatment was only that of a certain lessening of the pain, inasmuch as there was an increased sensitiveness for a few hours after the irradiation and a distinct lessening of the painfulness later; a cure or a permanent diminution of the pain was not possible. Therefore, in every case which presents such symptoms and such a course, two to four attempts with quartz lamp irradiation should be made.

Death From Electrical Currents.—Karl Meixner (*Wiener klinische Wochenschrift,* July 13, 1922) asserts that the resistance of different individuals to the electric current varies exceedingly and, therefore, there is a great difference in the strengths of lethal currents. An analysis of four cases, in which death resulted from electricity, showed that all the patients had organic lesions, not necessarily severe but sufficient to lower the general resistance, such as are usually designated as of unknown cause; in these cases even weaker currents may have a lethal effect in the presence of such lesions. The body constitution and the inferiority of the general body structure apparently play an important part in death from electricity; the predisposing factors are usually cardiac disturbances.

PEDIATRICS.

Vomiting in Newborn and Young Infants.—C. Page Lapage (*Practitioner*, July, 1922) says that if the vomiting is metabolic in nature, a period of starvation, the length of which depends upon the severity of the symptoms, must be adopted, and, in the meantime, the dietetic error eliminated. If there is overfeeding with breast milk, the mother's diet must be revised, and, if necessary, the breast pump used to diminish the amount taken by the infant. Some breast milks are of bad balance; for instance, a thin, watery milk often contains too much protein and too little fat; in such cases, the addition of fat in the form of milk to the mother or mixed feeding may be of great value.

For protein vomiting sodium citrate (two grains to the ounce of milk) is a useful remedy, though it causes constipation. Heat diminishes the size of the curds, and increases their digestibility. This is why dried and cooked milks are so often more digestible than fresh milk. Peptonizing or the use of predigested foods may help. Finally, resort may have to be made to whey and meat juice, or whey and albumen water, with albulactin, which forms a useful protein addition for curd vomiting babies. Sometimes a sweetened, condensed milk is useful before coming down to whey. Whey mixtures are hardly sufficient to nourish a baby for long, and after four days, or, at the most, a week, it is better to find some more sustaining food.

For fat vomiting, which is common, milk and water mixtures without any added cream can be used. One of the most useful mixtures for out patient babies is a milk and water mixture, sterilized for thirty minutes and sweetened, with no cream but with extra fat in the form of emulsion of cod liver oil, half a teaspoonful three times a day to infants from six months to one year. Many babies who vomit on a full fat mixture will take this well, because not only is the protein rendered more digestible by cooking, but also the fat of cows' milk, which is the real difficulty, is reduced in amount and replaced by the more digestible cod liver oil emulsion. In the same way, when the full cream dried milks cause vomiting, the half cream dried milks may succeed. When ordering two or three days' starvation to restore tolerance, water can be used at first. Many cases of vomiting are accentuated by giving babies milk, when they are really thirsty and in need of water.

Basal Fibrosis in Children.—G. T. Hebert (*Lancet*, June 10, 1922) states that the basal pneumonic residues in children appear in roentgenograms as an increased translucency instead of the usual and expected opacity and are often mistaken for tuberculosis. A roentgenogram in such a case showed the following features: 1, displacement of the heart half an inch to the right; 2, increased translucency of the lower half of the right pulmonary field; 3, absence of the smaller shadows of the bronchial tree and replacement of the larger by a fine linear marking; and 4, shadows suggesting some increase of fibrous tissue round the bronchi at the root of the lung, with slight dilatation of the bronchioles at the edge of the translucent area. This finding may be explained by the fact that probably the normal shadows of fibrous tissue are not seen because the surrounding lung parenchyma is avascular, emphysematous, edematous, or in some other condition making it unusually translucent. From the pathological viewpoint, edema is most likely to be the cause; clinically, the finer crepitations may be produced in collapsed areas, but the medium sized and typically moist râles suggest the presence of fluid in structures larger than the alveoli. Possibly the interstitial tissue becomes edematous, with the resulting roentgenographic picture described above. This translucency is important evidence in the differentiation of nontuberculous fibrosis from tuberculous fibrosis of the lungs as it does not occur in the latter.

Regeneration of Blood in Infancy.—Hans Opitz (*Monatsschrift für Kinderheilkunde*, November, 1922) attempted to determine the effect of the well known factors that favor the regeneration of blood in the anemic conditions of infancy. This is still a subject of extensive discussion. Considerable differences are noted in the growing and mature organisms: drug therapy, which plays an important part in the anemias of adults, is of considerably less importance in the anemias of infants, whereas the alimentary factors most necessary for the development of anemias in early infancy are relatively insignificant in later life. The amount of transfused blood necessary to bring the number of corpuscles in the child to normal were computed by the author and this dose was repeated after four to ten days as often as seemed necessary. The results were very good except in two cases of lymphosarcoma and myeloid chloroma. The author believes that the injected corpuscles are not destroyed, because the signs of regeneration, such as erythroblasts, basophilic stippling, etc., disappear from the blood. It may be that the injected blood takes up part of the function of the blood and gives the bone marrow time to rest and recover. A mixed diet and a moderate reduction of the milk may hasten recovery.

Acrodermatitis Chronica Atrophicans and Its Relation to Scleroderma

By FRED WISE, M.D.,
New York,
Assistant Professor of Dermatology and Syphilology, College of Physicians and Surgeons, Columbia University; Chief of Clinic, Department of Dermatology and Syphilology, Vanderbilt Clinic.

Acrodermatitis chronica atrophicans is sometimes confused with scleroderma. Some believe it to be only an aberrant form of scleroderma. For example, Sutton, in his textbook, says: "The disorder is to be differentiated from scleroderma, particularly scleroderma of the edematous type. Arndt, who has investigated the question carefully and exhaustively, holds that confusion can occur only in the earlier stages of the disease—an opinion which is shared by Finger and Oppenheim. Herxheimer and others hold that the two maladies are often practically indistinguishable in the atrophic stage. Judging from the result of my own studies, I should say that some cases of acrodermatitis chronica atrophicans, as the disease was originally described by Herxheimer and Hartmann, cannot be differentiated from the edematous form of scleroderma at any stage. In fact, the two affections are probably identical."

But this view is by no means one which is unanimously accepted. To judge from the numerous papers bearing such titles as Cutaneous Atrophy and Scleroderma or Acrodermatitis Chronica Atrophicans and Scleroderma, one would infer that there had been left no loophole for further controversy about the matter. Nevertheless, a perusal of the relevant literature, together with certain definite impressions gained from the discussions of a number of cases of acrodermatitis atrophicans in various dermatological societies, reveals the fact that not only is there no unanimity of opinion on the subject, but that a great diversity of opinion evidently exists in the minds of many dermatologists.

CLINICAL MISCONCEPTIONS.

To understand the clinical picture presented by acrodermatitis chronica atrophicans and its various manifestations in different stages of the disease, it will be necessary to clear up certain misconceptions which prevail, even among those who specialize in dermatology.

To begin with, it is a fact that only about one third of the cases of acrodermatitis chronica atrophicans reported in the literature present evidences of sclerotic skin; the other two thirds are examples of ordinary, noncomplicated atrophia cutis—dermatitis atrophicans progressiva. In approximately two thirds of the cases, therefore, sclerotic tissue, scleroderma or hard skin is conspicuous by its absence, throughout the course of the malady. Hence it must be evident that not all cases of acrodermatitis chronica atrophicans are "probably identical" with scleroderma, since one is essentially an atrophying process and the other essentially a sclerosing process.

The next important thing to consider is the fact that the sclerosis of the skin occurring in isolated or diffused areas in acrodermatitis atrophicans, takes place in areas of skin which have already undergone various degrees of atrophy: the sclerosis is consecutive to the atrophy. Therefore, since true scleroderma cannot begin with atrophy, these sclerotic patches cannot be true scleroderma. This statement applies to those sclerotic patches which appear within the domain of the atrophying dermatitis; usually on the upper and lower extremities. The question of sclerodermalike lesions on the chest, back and other parts of the trunk, will be discussed later.

SCLERODERMA AND ATROPHY.

In a certain proportion of cases of scleroderma, the end stage of the process is characterized by atrophy of the affected areas of skin. Does scleroderma always end up with atrophy? Probably not. Of 508 cases of scleroderma recorded by Lewin and Heller, only thirty-one showed evidences of atrophy. But the mere fact that some sclerodermas terminate in complete atrophy, in no way justifies the assumption that these atrophic lesions bear any clinical or nosological relationship to the atrophic lesions of acrodermatitis atrophicans. Indeed, it

is my belief that the final atrophy of scleroderma can be differentiated from the atrophy of dermatitis atrophicans on clinical grounds alone, at least in most instances where an actual comparison can be made with two patients viewed side by side. In this belief I am supported by some of my colleagues. The smooth, soft, velvety feel, the ease with which the skin may be lifted in fine folds, the peculiar shade of color, the "crumpled cigarette paper" appearance—in short, the anetoderma of Jadassohn—are characteristics of acrodermatitis atrophicans, but are lacking, in greater part, in the clinical pic- or even as the atrophic end stage of scleroderma,

INDIVIDUALITY OF THE TWO DISEASES.

Granting, however, for the sake of argument, that a given area of acrodermatitis atrophicans is clinically indistinguishable from a given patch of scleroderma in its atrophic period, what justification is there for the belief, expressed by some, that the two diseases are not only related, but sometimes identical? None whatever. Regardless of the end stages of both affections, one still remains an atrophying dermatitis, the other still remains a scleroderma. If we were to follow such a course of specious reasoning in making our clinical diagnoses and in the teaching of our students, to be consistent we would be constrained to label the atrophic end stage of pityriasis rubra of Hebra as atrophia cutis, or even as the atrophic end stage of scleroderma, since Hebra's disease may also terminate in anetoderma. One might go further and say the same of a healed and atrophic favus of the scalp, or of a healed lupus erythematosus, or even of leprosy.

THE DIAGNOSIS OF ACRODERMATITIS CHRONICA ATROPHICANS.

The diagnosis of acrodermatitis chronica atrophicans is made, clinically, not by focusing one's eye and concentrating one's mind on a patch of hard, waxy yellow, bound down skin on the leg, or about the elbow, and ignoring the other phenomena which go to make up the whole, but rather by considering the sum total of clinical symptoms, together with their definite relations to the chronological data furnished by the patient. A child who is afflicted with xeroderma pigmentosum, for example, dies of cancer; but still the diagnosis remains xeroderma pigmentosum, no matter how much the cancer may obtrude itself into the picture, no matter how it may dominate and overwhelm all the other features of the disease. A patient with Recklinghausen's disease may present many different types of lesions: freckles, angiomas, birthmarks, soft and hard tumors, adenoma sebaceum, even bone changes and cerebrospinal disturbances—the whole symptom complex constituting Recklinghausen's disease. So with acrodermatitis chronica atrophicans, the diagnosis is established by recognizing the existence of a change in the skin manifesting itself clinically by a primary atrophy (histologically, by a primary dermatitis); once this primary atrophy is established and recognized as such, what follows in the course of the malady does not in any way alter the diagnosis, any more than the advent of cancer alters the original diagnosis of xeroderma pigmentosum.

In acrodermatitis atrophicans, different and diversified clinical phenomena may appear, consecutive to the primary atrophy of the skin. Of these, the most frequent and the most prominent are the patches of hard, bound down, indurated tissue, occurring chiefly on the extremities, resembling scleroderma; there may be a superimposed scaling and eczematous dermatitis; there may be, late in the course of the disease, several bluish red, hemispherical, pea to walnut sized, smooth, indurated tumor masses about the elbows or knees; rhagades, even deep ulcerations, followed by carcinoma or sarcoma may appear (as has been recorded) about the ankles; these various consecutive clinical phenomena notwithstanding, the disease still remains acrodermatitis chronica atrophicans.

THE INITIAL STAGES.

To revert to the initial stages of the two maladies, its has been said by some writers that the initial stage of scleroderma, manifested in some instances by edema, is indistinguishable from the initial stages of some cases of acrodermatitis atrophicans, manifested by edematous, circumscribed, soft, bluish red, "boggy" tumors and infiltrations. These are the preatrophic infiltrative masses to which Herxheimer and Hartmann first called attention, in 1904. I have had the opportunity to observe, over a period of years, what is probably the most pronounced example of such preatrophic infiltrative tumors recorded in the literature, and have published a study of the clinical and histological features of this patient's disease, together with illustrations of the skin and of the microscopic sections. I have observed two more patients presenting these preatrophic infiltrations. Without going into tiresome and unnecessary details, I can say that as far as the clinical appearances in these three patients are concerned, these boggy masses reminded me no more of the edematous stage of scleroderma, than they did of scabies. What they did remind me of, were the articles on acrodermatitis chronica atrophicans, by Herxheimer and Hartmann, Herxheimer and Schmidt, Herxheimer alone, and Finger and Oppenheim, to say nothing of numerous other publications on the subject, which I had read. That they did *not* remind me of scleroderma is not for lack of having seen scleroderma in all its manifestations during a score of years' work in the large clinics of New York. No; the reason they did not bring scleroderma to my mind was simply because they did not look anything like any scleroderma I had seen until then, or expect to see in the future.

ACRODERMATITIS CHRONICA ATROPHICANS AND DIFFUSE ATROPHODERMA.

Acrodermatitis chronica atrophicans, with its diverse clinical manifestations, has been described in scores of publications by European and American writers. Prior to 1902, the year of the appearance of Herxheimer and Hartmann's first paper, the cases were reported under various titles: an atrophic condition of the skin of the legs; symmetrical cutaneous atrophy; idiopathic atrophy of the skin; diffuse idiopathic atrophy with scleroderma; diffuse atrophoderma; dermatitis atrophicans, and so forth. In society transactions, several cases in America were recorded as cases for diagnosis. In 1905, Herxheimer published another paper in English, in *The Journal of Cutaneous Diseases,* and since then, the cases of acrodermatitis chronica atrophicans began to be differentiated, in this country, from those of "diffuse idiopathic atrophy of the skin," although not consistently; for example, Irvine's case, reported as idiopathic atrophy of the skin, was an example of acrodermatitis atrophicans. The differential diagnosis between the two clinical entities was discussed in a paper which I published in 1915. The chief points in differential diagnosis are the following: In acrodermatitis atrophicans there is often a preatrophic inflammatory process, characterized by the formation of edematous, elevated, smooth, bluish red, boggy tumors or infiltrations; these occur on the upper and lower extremities, where the disease almost invariably begins; hence Herxheimer's designation, acrodermatitis. Almost always, when the process begins on the feet, the toes remain unaffected, the atrophy beginning at the bases of the toes and progressing over the feet, ankles, legs and thighs, extending often to the pubic region in front, and over the buttocks, to the iliac crests, behind. In rare instances, however, the entire trunk may be implicated. (Such an example will be described further on.) Strips of sclerotic skin in the form of ulnar bands, less frequently tibial bands, sometimes appear. Diffuse and isolated plaques and patches of sclerodermalike skin may appear in the midst of tissue which has already undergone atrophy; the skin of the dorsi of the feet, the ankles and the lower third of the legs is often hard, waxy looking and bound down to the underlying structures; at times this is also seen on the forearms. In the end stages, paraarticular fibrous nodules sometimes occur, chiefly about the elbows and knees; one of the best examples of these nodule formations was described by Ketron, of Baltimore, and several have been described by Oppenheim, of Vienna, who was the first to call attention to them. Whether the postatrophic, sclerodermalike lesions ever become finally transformed into atrophic tissue is a moot question; Oppenheim does not think that such a change ever takes place; I have never seen any evidences to support such a contention.

Diffuse idiopathic atrophy may also occur on the extremities, but it does not do so uniformly, as in acrodermatitis atrophicans. Usually the process first appears on the trunk, spreading insidiously, until the entire skin may be implicated. There are no preatrophic inflammatory infiltrations or tumor formations. The ulnar band is rarely encountered; the sclerodermalike infiltrations are absent in the large majority of cases; when present, the surface of these areas is much more transparent, soft and wrinkled than that of acrodermatitis atrophicans: the postatrophic, paraarticular nodules may, according to Finger and Oppenheim, appear in both forms of atrophia cutis. In the end stages of these two forms of cutaneous atrophy, the clinical appearances resemble each other so closely that a differentiation is difficult or not possible: both are designated as dermatitis atrophicans diffusa et progressiva.

A thorough presentation of the whole subject of cutaneous atrophies was published, in the form of a monograph, by Finger and Oppenheim, in 1910. Nearly all of the cases of acrodermatitis atrophicans published in the world's literature, to that year, are reviewed in this little book.

AMERICAN LITERATURE.

In going over the records of cases published in the United States I found that approximately sixty-five cases of acrodermatitis chronica atrophicans have been reported, under various titles, in American journals. About fifty of these were encountered in New York City. Of these fifty patients, I demonstrated thirteen before the local dermatological societies during the past ten years; the great majority of these were from Dr. Fordyce's service at the Vanderbilt Clinic.

Instances of the disease are probably seen in all large centres of population in the United States, especially those having a large quota of immigrant residents. I should judge that in the city of New York alone, with its enormous alien population, there are constantly between one hundred and one hundred and fifty cases of acrodermatitis atrophicans. The disease occurs almost exclusively in the foreign born; the nationalities are chiefly Russian, Polish, Roumanian, German, Austrian, Swedish, Norwegian and Irish. Frank examples of the malady have been reported, so far as I know, in only two American born citizens. In New York City, with its large proportion of Central European immigrant Jews, one might easily get the impression that the disease predominates in that race; but an analysis of the situation does not bear this out. In a recent paper on this subject, Pautrier and Eliascheff stated that of seventy cases described in the literature, two were reported from America [in Americans?], two from France, three from Italy, while all the rest emanated from German, Austrian and Polish sources. During a year's sojourn in Strasbourg, they encountered two examples of the disease. In Germany, Max Jessner presented six patients before the *Schlesiche dermatologische Gesellschaft,* July 8, 1922, and said that during the first six months of the year 1922 he had encountered seventeen cases of the disease.

Thus it is evident that, little as we know about the malady, it is by no means a rare one.

ACRODERMATITIS CHRONICA ATROPHICANS AND SCLERODERMA.

Neither Finger nor Oppenheim, in their separate publications and in their joints monograph, admits that the sclerotic areas of acrodermatitis atrophicans are true scleroderma. Oppenheim goes so far as to say that he does not believe that the two diseases ever coexist in the same patient; later on, he modifies the statement by adding that if they do apparently coexist, it is purely a coincidence. On the other hand, the simultaneous occurrence of both processes has been reported by Rusch, Arndt, Herxheimer, Nobl, and, in this country, Kanoky and Sutton, Kingsbury and others. Heuck (Germany) reported and illustrated such an example in the *Ikonographia Dermatologica,* but made no histological examination of the sclerotic tissue; I consider Heuck's case to be one of ordinary acrodermatitis atrophicans with associated sclerotic lesions about the knees. In Nobl's case, microscopic sections of the indurated tissue taken from the back revealed what he called "keloidlike scleroderma." Sutton, from studies of microscopic sections from one of his patients, convinced himself that scleroderma formed a part of the disease. Sutton's histopathological findings are indisputable, but the description of the clinical features of his patients' dermatoses does not correspond with those of frank acrodermatitis atrophicans. Herxheimer and Schmidt wrote a critique of Sutton's paper and said:

"There exists a great diversity of opinion regarding the histological findings not only in dermatitis chronica atrophicans but in scleroderma. To quote Krzysztalowicz, who investigated diffuse scleroderma, a comparison of the latter with the (pathologically) closely related process, atrophia cutis idiopathica diffusa, leads to no elucidation. In both the changes in the beginning affect the vessel walls and their surrounding tissue; both lead to the disappearance of the adipose and subcutaneous connective tissue, and merging of the latter with the cutis. Then the process diverges in that, in atrophia cutis the atrophy of the collagen and glands follows rapidly, leading to thinning of the skin with complete disappearance of the elastic tissue, while in scleroderma, atrophy of the collagenous tissue progresses slowly, with, however, the final sacrifice of these and the elastic fibres.

"In conclusion we would emphasize that the clinical picture of idiopathic atrophy and the atrophic stage of scleroderma may present many similarities. We are, however, far from holding the opinion that acrodermatitis and scleroderma in the atrophic stage are identical, as maintained by Vignolo-Lutati."

In Kingsbury's patient the clinical appearance was that of a combined atrophia cutis and scleroderma, the latter occurring within the territory of the acrodermatitis atrophicans, namely, on the upper and lower extremities. No sections of the sclerotic tissue having been made, the interpretation of the case is inconclusive.

Scholtz (Los Angeles) recently summarized the various points of the controversy as follows:

"A feature that gives rise to the most confusion and greatest difficulties in the differential diagnosis of acrodermatitis chronica atrophicans is the sclerodermalike infiltration. In many cases reported under a diagnosis of acrodermatitis chronica atrophicans, sclerodermalike infiltrations were so marked as to give rise to a doubt whether they were atypical cases of atrophic scleroderma or a combination of acrodermatitis chronica atrophicans with scleroderma. In the writer's opinion, the infiltration in acrodermatitis chronica atrophicans is not identical with the sclerodermic infiltration and can be differentiated, both on clinical and pathological grounds.

Clinically, a typical case of scleroderma and a typical case of acrodermatitis chronica atrophicans differ so widely that they can hardly give rise to confusion. It is the atypical and transitional cases that render a differentiation at times difficult. But even then, irrespective of characteristic distribution, there is one clinical symptom that can be taken as a fundamental differential feature; namely, the presence, in acrodermatitis chronica atrophicans, of a diffuse inflammatory hyperemia, which has a tendency to extend beyond the area of infiltration. Scleroderma proper is a purely degenerative process and not an inflammatory one, and in its uncomplicated form it is manifested by a whitish color, paler than the surrounding tissues, and not by an inflammatory redness. A dark red and bluish hue, due to the network of translucent veins shining through the atrophic skin in the later stages, has nothing to do with the inflammatory redness preceding and accompanying the infiltration stage.

Another feature of equal importance in the differentiation of true scleroderma from acrodermatitis chronica atrophicans in the infiltrative stage is the surface marking of the patch. In scleroderma it is smooth, shiny, waxy; in acrodermatitis it is rough and shows a branlike exfoliation of mild degree. In fact, in its early stages, acrodermatitis may resemble somewhat a mild exfoliating dermatitis.

Histopathologically, a confusion may arise only in the atrophic end stage, the difference in the early stages being marked enough to prevent confusion. In scleroderma it is universally agreed that there are practically no changes in the epidermis, and that the hypertrophy of the collagen and elastic fibres is the most constant and characteristic change. In acrodermatitis there is no such increase in these elements, even in the infiltrative stage. On the contrary, an early disappearance of the elastic fibres is regarded as the most constant and characteristic histological feature. It is only in the atrophic end stage that the histological picture in both conditions shows the same phenomenon of the decrease of elastic fibres due to the pressure of the infiltrate. In this stage a differentiation is difficult and is to be made on clinical grounds.

Thus, both clinically and pathologically, it would seem to be justifiable to regard the infiltration in acrodermatitis as a different process from that of scleroderma, even though at certain periods there is some clinical resemblance. In some cases, such as those reported by Kanoky and Sutton and by Kingsbury, it must be admitted that there is a possibility of the coexistence of both conditions, possibly due to the same etiological factors.

The sclerodermalike infiltrative process observed in acrodermatitis is not identical with scleroderma, either clinically or pathologically, though the combination of acrodermatitis and true scleroderma is possible."

THE SCLEROSIS IS CONSECUTIVE TO THE ATROPHY.

Oppenheim described a female patient, aged twenty-seven, who presented an acrodermatitis atrophicans of the lower extremities. The process began seven years previously. The skin over the dorsi of the feet, about the malleoli and the lower third of the legs was hard, bound down, of a yellowish white color, and could not be raised into folds. Here it resembled scleroderma. The skin of the upper portions of the legs, the knees and thighs presented the usual soft, flabby, velvety, bluish red, atrophic picture with its associated crumpled cigarette paper appearance—anetoderma. This was a typical example of acrodermatitis atrophicans, presenting the two clinical features so often observed: the atrophy and anetoderma of the skin of the upper part of the legs, knees and thighs, and the sclerotic, bound down skin of the lower portion of the legs, the ankles and the dorsi of the feet.

How is this clinical picture properly interpreted?

Is it one of atrophia cutis, or of scleroderma, or of both conditions occurring simultaneously?

In this patient, as in all other presenting areas of sclerotic and atrophic skin on the same limb, the outstanding fact was definitely ascertained from the patient's history, that the atrophy preceded the sclerotic change for a period of years. In one of my own patients, the skin about the ankles first began to harden and become bound down fully twelve years after the atrophic stage had been in existence in that location. The sclerosis of the skin is therefore evidently a process consecutive to the atrophy, and hence cannot be regarded as a true scleroderma. The sclerosis may supervene shortly after the establishment of complete atrophy; or months or years later; or it may not appear at all; in the last case, the patient may have acrodermatitis atrophicans for thirty years and die of old age, without ever manifesting the least evidence of sclerosis either within the territory of the acrodermatitis atrophicans, or on any other portion of the integument. I have had under observation two patients with long standing acrodermatitis atrophicans, in neither of whom sclerotic patches appeared, despite the age and the chronicity of the affection on the lower extremities. Assuming that my diagnosis in these two patients is correct, what possible relationship can there be between their chronic, progressive cutaneous atrophy of the lower extremities and a scleroderma? Aside from a presumptive etiological relationship—the possibility of endocrinous disturbances bringing about both conditions—there exists no relationship between the two conditions, at least in my opinion. And this purely clinical viewpoint, put forth by several experienced and very competent dermatologists over twenty years ago, still maintains its hold among those who have the advantage of seeing the largest number of cases. Among these I venture to say that Finger held an enviable reputation; and Finger, in his publications, strongly stresses his belief that there is no relationship between true scleroderma and the sclerosis accompanying acrodermatitis atrophicans; and that the diagnosis of scleroderma, applied to anetoderma, is always an erroneous one, whether the disease is encountered in its earliest stages, or in the stage accompanied by sclerotic formations, or by fibrous nodular lesions about the elbows and knees. In one of his papers he said:

"With regard to the relationship existing between anetoderma and scleroderma we have already called attention to the fact that a certain group of cases, the socalled morphea of French and English authors, give the impression of being transitional stages between the two diseases. It would be necessary to demonstrate a more intimate relationship between these two processes to convince me that anetoderma and scleroderma may exist conjointly in the same individual. Their simultaneous occurrence would point to a common etiology. Such, however, is not the case. We have mentioned the fact that the diagnosis of scleroderma has been made erroneously with reference to the infiltrated lesions of acrodermatitis chronica atrophicans, as well as the tense forms of atrophy which occur in the course of diffuse anetoderma in those areas in which the skin is naturally (physiologically) more or less tense and drawn—namely the dorsum of the foot and the leg, anteriorly. After a thorough perusal of the literature I am unable to convince myself that a combination of the two forms of tissue changes may coexist; and if such a change does occur it is open to question whether an etiological factor is common to both, or whether we are dealing merely with a coincidental appearance of two unrelated dermatoses."

HISTOPATHOLOGY OF THE SCLEROTIC TISSUE.

So much for arguments based on, 1, clinical observation; 2, the patient's history, and 3, the literature. We shall now consider the histopathological findings in: 1, sclerotic tissue within the territory of acrodermatitis atrophicans, and 2, sclerotic tissue outside the territory of acrodermatitis atrophicans.

The minute structure of the areas of sclerotic tissue within the domain of the atrophic portions of the skin—the extremities—has been very thoroughly described in a number of European publications within the past ten years. Studies of such sections, taken from two of my patients, were published in a paper by me, and in another jointly with Dr. Snyder. In these, the various differences between the microscopic structure of the sclerotic tissue and that of scleroderma are dealt with, but only in a general way. One of the best descriptions dealing with this phase of the subject is that of Oppenheim; and as his findings are discussed in minute detail, they are of sufficient interest and importance to be transcribed here, at least in part.

HISTOPATHOLOGY OF SCLEROTIC AND ATROPHIC TISSUES.

Oppenheim excised a piece of skin from a patch of sclerotic tissue bordering an area of atrophic skin, on the dorsum of the foot, in a woman who had typical acrodermatitis chronica atrophicans. Thus half the section consisted of sclerotic, the other half of atrophic tissue.

Weak magnification revealed an apparently normal epidermis, which in some places ran in a straight line, in others in long wavy lines, and showing no evidences of rete pegs. The area with straight epidermis represented the sclerotic portion of the section, the wavy area the atrophic portion. Throughout the section the corium was widened; the connective tissue bundles were more dense in the deeper portions, and, in the sclerotic half of the section, they appeared also close under the epidermis. In the atrophic area, the connective tissue bundles in the subpapillary portion of the cutis were more delicate in appearance and were not so widespread. The cellular elements of the connective tissue were more numerous in the atrophic area, while the cellular infiltrations in this region were more sparse; in the sclerotic area these infiltrations were more numerous and more closely packed about the bloodvessels and glandular structures in the corium. Beneath the epidermis of the atrophic portion there were many dilated, thin walled vessels, filled with blood cells; in the sclerotic area, these were entirely absent.

With higher magnification it was seen that the epidermis as a whole showed little deviation from the normal; the cells of the stratum corneum were loosely attached, and, in the absence of the stratum lucidum and granulosum, they rested directly on the stratum mucosum. In the atrophic portion, the rete Malpighii consisted of seven to eight rows of cells, the basal cell layer was normal, and there was a sharply defined separation between epidermis and corium. The cutis consisted of straight, dense bundles, mostly running parallel to the surface, closely packed, and becoming denser toward the subcutis. In the uppermost layers, the lumina of the bloodvessels were almost entirely obliterated; they were surrounded by masses of plasma cells and round cells, extending to the upper border of the cutis.

In the atrophic portion the epidermis was thinner; the stratum lucidum and stratum granulosum were absent, the rete cells were flattened and in places composed of only three or four layers. The basal cell layer, devoid of rete pegs and corresponding to the wavy surface of the cutis, showed distinct evidences of edema. The connective tissue of the corium was here well supplied with cells and bloodvessels, being especially numerous just beneath the epidermis. Here also were seen numerous large and small dilated vessels filled with blood cells. There was no vascular obliteration. The cellular infiltration, especially about the bloodvessels, was much more pronounced in this portion of the skin; the infiltrations were less sharply defined and their bordering cells seemed to blend with isolated fixed connective tissue cells. In the cellular masses just beneath the epidermis were seen elongated spindleshaped cells, arranged in parallel rows and resembling fibroblasts. Among these were mononuclear leucocytes and capillary vessels.

The sweat glands were surrounded by plasma cells; mast cells were very few in number; some pigment was seen in the basal cell layer; isolated collections of hemosiderin occurred in the cellular infiltrates.

With respect to the elastic tissue, the microscopic findings were of greatest interest. In the sclerotic portion, not only was the elastic tissue preserved close up to the epidermis, but it actually was increased in amount. At the junction of epidermis and cutis, it formed a bordering strip of elastic tissue, such as Unna described in scar tissue. From this strip fine prolongations extended toward the surface, while downward prolongations also made their way in thick strands. They merged with the cellular infiltrates, being more dense at their peripheries. Toward the atrophic portion of the section, these strands became less and less pronounced in the deeper layers of the cutis, enmeshing only the denser bundles of connective tissue.

In that portion of the section which corresponded to the line of junction of the atrophic and sclerotic areas of skin, these strands of elastic tissue appeared as though they had been cut down upon, from above; in other areas they were so densely packed that almost no connective tissue bundles were visible between their strands.

In the atrophic portion (except in certain places to be mentioned later) there was complete absence of elastic tissue in what had been the papillary and of connective tissue in the deeper layers of the cutis there were a few sparse elastic tissue strands, widely dispersed here and there. Futher down in the subcutis they were more numerous, but here also were zones entirely devoid of elastin. The strands were disposed mostly in direct relation to the infiltrating cells or noninfiltrated bloodvessels.

In many places the elastic tissue appeared in the form of clumps, little broken down heaps and small particles; in isolated spots in the tissue there were also delicate, fine, elongated, pale staining fibres, running along with bundles of connective tissue. In other portions of the cutis were seen masses of elastic fibres which were stained deep black, arranged in dense and irregular clumps, not disposed in relation to the connective tissue bundles, some of them surrounding the cellular infiltrations, others lying entirely free. Other masses of fibres were arranged in various bizarre shapes and designs. Islands of elastic tissue were especially prominent in two or three places just beneath the epidermis; these were the only instances in which elastin could be demonstrated above the subpapillary layer, in the atrophic portion of the skin. In the cutis and subcutis the elastic tissue was in great part preserved about the vessels, although it showed degenerative processes here and there; in some vessels in which the intima was thickened, there were deeply stained dense elastic fibres within the vessel walls.

The significance of these findings is not easy of interpretation, although that pertaining to the atrophic area, in which the elastic tissue is wholly absent, is not so difficult. In the atrophic area the histological findings correspond to those of dermatitis atrophicans; only the well marked development of connective tissue in the deeper layers of the cutis, does not rightly belong in the picture. This development of connective tissue is to be regarded in the light of a secondary manifestation beginning in the deeper layers of the cutis and gradually forcing itself toward the surface. This is evidenced by the presence of bloodvessels with their thickened walls and their dense plasma cell infiltrations, gradually decreasing toward the surface. The bloodvessels of the subpapillary and prexisting papillary layers are merely dilated, their walls being unaltered, showing almost no infiltration, or at most a moderate round cell infiltration. Here, the skin is, clinically, still atrophic, bluish red, wrinkled and easily movable over the subjacent tissue, namely, the thickened reticular layer of the cutis.

In the stiffened, white, anemic portion, this sclerosing process, beginning in the deep portion and advancing to the superficial region of the cutis, has extended close to the epidermis; in this area the bloodvessels are compressed and obliterated, surrounded by dense plasma cell aggregations and fibroblasts. It seems that this sclerosing process has its origin in the bloodvessels, about which the embryonal tissue, giving rise to the connective tissue, first develops. These vessels show distinct evidences of endovasculitis and perivasculitis.

The histological findings pertaining to the elastic tissue are the hardest to interpret. How is one to explain the aggregations of deeply stained, dense elastic strands lying in the midst of an elastin free connective tissue; and the presence of broken down and disintegrated clumps of fine, delicate and faintly staining strands, in the sclerotic portion of the section?

It is best first to consider the elastic strands about the bloodvessels and their infiltrating cells. Here they are exceptionally dense, staining a deep black, running partly parallel to the connective tissue bundles, partly in irregular and haphazard directions, sometimes extending radially, apparently emanating from the infiltrate. These manifestations are especially well marked at the junction of the atrophic and sclerotic portions of the section. From these appearances, one may safely assume that there is a new formation of elastic tissue, derived from the vessels and their infiltrates, and not from preexisting, old elastic tissue strands. Similar findings were recorded by Cesaris Demel in sclerotic tissue.

However, the question whether the newly formed elastic tissue originates in the cellular infiltrations, or intracellular substance, or in the elastica of the bloodvessels, is not germane to the present problems, although the evidence is strongest in favor of a blood vascular origin. Thus the newly formed elastic tissue begins about the vessels and their infiltrates, extends prolongations into the connective tissue, eventually disposing itself in the manner already indicated, in the sclerotic part of the skin.

"How, then, is this sclerotic change to be regarded from the histopathological viewpoint?

"It cannot be interpreted as an ordinary or hypertrophic scar, for the elastica in scar tissue is either diminished or wholly absent. It must, therefore, be regarded in the light of an end product of a sclerosing process, affecting the atrophic skin; this process has its origin in the deeper bloodvessels of the cutis and is accompanied by a regeneration of elastic tissue strands.

"Furthermore, this sclerosing process, having its starting point in the deeper bloodvessels and extending toward the surface, can evidently not be scleroderma. Its development within the atrophic territory of skin; the fact that it begins in subcutaneous tissue; the dense plasma cell infiltrations about the vessels; the flattening and obliteration of the papillæ; the condition and disposition of the elastic tissue—all speak against the assumption that we are dealing with a true scleroderma. If true scleroderma were to be taken into consideration, it should be regarded from the viewpoint of an adventitious complication—the simultaneous occurrence of two different diseases.

"The opinion entertained by some observers, namely, that the atrophic process represents an end stage of an existing scleroderma, is negated by the patient's history, by the histopathological findings, and by data forming the sum and substance of the literature."

SCLEROTIC LESIONS OTHER THAN THOSE OF THE EXTREMITIES.

Some cases of acrodermatitis chronica atrophicans have sclerotic lesions not only on the extremities, but also on the trunk, the abdomen, chest and back. Clinically, these resemble true scleroderma or morphea much more than do the lesions on the extremities. They are often sharply defined, their borders are often clean cut, their color is that of old ivory and they are markedly indurated. The surface is smooth, glistening and free of gross dilated vessels. But their appearance differs from that of ordinary scleroderma circumscriptum, in that, instead of being surrounded by normal skin, they are surrounded by, and actually imbedded in, skin which already shows evidences of atrophy and hyperpigmentation. Here again, as on the extremities, the sclerotic formation is consecutive to the atrophic process.

A patient illustrating this condition is at present under our care at the Vanderbilt Clinic. She is aged sixty-eight, and has a typical acrodermatitis atrophicans which began about ten years ago. Beginning at the bases of the toes, the skin of the entire lower extremity is involved in the atrophic process to a marked degree; the skin of the buttocks, abdomen and chest, which has only recently been invaded, presents unmistakable evidences of early atrophy, accompanied by marked hyperpigmentation; but there are as yet no evidences of anetoderma. On the buttocks, abdomen and chest are several distinctly infiltrated, sharply defined patches of sclerotic skin, closely resembling morphea. The skin below the clavicles and over the sternum presents a peculiar mottled appearance, closely simulating certain cases of dermatitis lichenoides chronica atrophicans.

It seemed to be especially desirable to study a section of skin obtained from sclerotic tissue located outside of the area of typical acrodermatitis atrophicans, to enable one to study its histopathological features as compared with those of true scleroderma. A section was removed from such a patch on the patient's right breast.

HISTOPATHOLOGY OF LESION FROM THE BREAST.

Low power.—The epidermis is flattened, showing a thin and wavy outline. The stratum granulosum is represented by a single layer of cells, the thinning of the epidermis being at the expense of the prickle cell layer. The basal cell membrane is intact and sharply defined, showing, in places, an increase of pigment granules. The papillary bodies are absent. The bloodvessels in the upper cutis are few in number, moderately dilated, a few of the larger ones being surrounded by a cellular infiltrate. The lymphatics are moderately dilated. The bloodvessels in the deeper cutis are sparse, small, with thickened wall. From epidermal layer to fatty layer, the collagenous tissue is composed of wavy strands, many of them dotted with isolated fibroblasts; the bundles of connective tissue are in part parallel, in part they run in different directions. In between these bundles of connective tissue are seen more faintly stained and less clearly defined strands of collagen. In the upper portion of the cutis the collagenous bundles are more closely packed than those below, the latter being arranged more in a parallel course; they are thicker than those above and the intrafascicular spaces are wider. Near a remnant of a sebaceous gland, the arrector muscle seems well preserved, the gland itself being surrounded by dense connective tissue bands. Only one follicle is preserved, and it is surrounded by a cellular infiltrate. The nerve structures of the deeper cutis are intact.

General view, low power.—These findings point to an inflammatory process, resulting in a sclerosis of connective tissue, which is not uniform in character. In the upper portion of the cutis, the sclerotic process is characterized by the formation of more or less distinct strands or bundles of collagen, while in the lower cutis there is a more uniform involvement of the collagenous tissue as a whole.

High power.—The epidermis is composed of from five to seven rows of cells, the granular layer represented by a single row of cells. There is neither parakeratosis nor hyperkeratosis. The vessel walls in the upper portion of the cutis are thickened, due to edema rather than to hyperplasia; the walls of most of them are indistinct and somewhat glassy in appearance. The walls of the deeper blood vessels are homogeneous in appearance. The endothelium of all of the vessels is swollen, projecting into the lumina, causing partial occlusion of most of those seen beneath the epidermis, in the upper cutis. The infiltration is moderate, chiefly about the bloodvessels, predominantly consisting of round cells; but some of the infiltrations also show a considerable sprinkling of plasma cells. The collagen of the upper cutis appears in distinct strands, of which the fibrils are well defined; in the deeper portion of the cutis, the fibrillar structure is much less apparent. These strands for the most part are homogeneous in appearance, showing a bluish tint with the hematoxylin eosin stain. This appearance is attributed to the formation of collastin. In the upper cutis, some of these connective tissue bundles are distinctly granular, appearing to be undergoing disintegration or crumbling—also a feature of collastin change. The upper cutis contains numerous fibroblasts. In the deeper cutis are deposits of granular substance lying in between the bundles of degenerated collagenous tissue—a breaking up of the collagen.

Elastic tissue.—The elastica is preserved from epidermis to fatty layer, and appears to be less well defined about the areas of infiltrations. With the high power, the fibrils are seen as fine, broken tendrils, running up to the epidermal layer, in some areas well defined, in others indistinct. In the regions of the perivascular infiltrations, the elastica is, for the most part, absent; but in some areas, the elastica is seen to come quite close to the bloodvessels, appearing as small fibrils, fine clumps and irregular deposits of granular substance. Here and there, fibres are seen apparently emanating from clumps of infiltrate, but none coming directly from the vessel walls themselves. The upper corium presents long strands of elastic fibres running parallel to the connective tissue bundles, with wavy outlines. In areas where the collagen is crumbled and broken up, the elastica has a tendency to form clumps.

In the bloodvessels of the deeper cutis, the vascular elastic fibres are preserved, but appear to be swollen; in some bloodvessels there is a distinct ring of fragmented and granular elastic tissue. Throughout the entire area the fibres are more or less fragmented, coarse, swollen, and in places, form clumps. About a sebaceous gland the elastic fibres seem to be unaltered.

Although it was not possible to demonstrate a direct relationship between newly formed elastic tissue fibres and existing fibres in the walls of the bloodvessels, the histopathological structure of the sclerotic patch on the breast of my patient will, on comparison, be seen to correspond in all essential details with the histopathological changes of sclerotic tissue removed from the foot. With the exception of the changes described with reference to the collastin formation, the structure of the tissue from the isolated patch on the breast is practically the same as that described by Oppenheim, in a specimen removed from the sclerotic area of the foot.

SUMMARY AND CONCLUSIONS.

Acrodermatitis chronica atrophicans, a variety of dermatitis chronica atrophicans diffusa progressiva, is a distinct clinical entity.

In a certain proportion of cases, sclerotic tissue appears about the ankles, lower legs, knees and forearms; this sclerotic tissue superficially resembles true scleroderma at times, but in reality it has not the character of true scleroderma, in any but the very last stage of development.

A small proportion of patients present sclerotic patches, not only on the extremities, but also on the trunk. These patches are located in skin which, as that of the extremities, has already undergone various degrees or grades of atrophy; their histopathological structure is practically the same as that of the scleroses of the limbs.

The histopathological structure of sclerotic skin, both from the extremities and the trunk, in patients with acrodermatitis chronica atrophicans, does not correspond to the structure of scleroderma in any of its clinical manifestations, with the possible exception of the terminal stage of complete atrophy, with its complete absence of elastic fibres.

The sclerosis is always a secondary phenomenon. It is conceivable that a patient with acrodermatitis atrophicans may also have scleroderma. If the areas clinically simulating scleroderma are imbedded (and hence surrounded by) atrophic skin, it is to be assumed that the sclerosis sprang from atrophic territory, hence cannot be true scleroderma. Should such areas appear as isolated, morphealike, well defined patches, entirely surrounded by normal skin, it may be assumed that they are manifestations of true scleroderma.

The doughy, boggy swellings and infiltrations which sometimes precede the atrophying changes in dermatitis atrophicans, do not resemble the edematous stage of scleroderma enough to cause confusion in diagnosis. The terminal paraarticular nodule formations about the knees and elbows have nothing in common with scleroderma.

Scleroderma becomes atrophic—and especially anetodermic—in only a very small proportion of cases; according to Lewin and Heller, thirty-one out of 508 cases. Whether it finally becomes atrophic or not, scleroderma bears no relationship to acrodermatitis atrophicans, since the first is a sclerosing process and the second an atrophying dermatitis.

In conclusion, I wish to acknowledge my indebtedness to Professor Fordyce for his permission to use the clinical and histological material from his clinic; to Doctor Satenstein for his aid in the interpretation of the sections; and to Dr. H. J. Parkhurst for his aid in collecting the literature.

A Study of the Death of the Full Time Extrauterine Fetus *in Situ* and Its Scientific Value

By JAMES OLIVER, M.D., F.R.S., (Edin.) F.L.S.,
London, England,
Consulting Gynaecologist to the Hospital for Women, London, and The Ilford Emergency Hospital, Essex.

The uterus is the organ destined by nature for the reception, lodgment, and development of the human ovum after fertilization, and for the safety and welfare of the mother and child it is so peculiarly endowed that with the gradual evolution of the product of conception it becomes remarkably well fitted for both gestation and parturition. Not infrequently, however, it happens that the fertilized ovum on its way toward the uterus becomes arrested and this arrest most commonly takes place in some portion of the Fallopian tube, a structure which anatomically and physiologically is ill suited for harboring and nourishing an actively developing oosperm. Arrested in such an abnormal situation it nevertheless attempts to adapt itself to these untoward conditions and strenuously endeavors to make the maternal tissues meet its needs and furnish it with all the nutrient materials it requires.

The Fallopian tubes—two in numbers—are situated one on each side of the uterus in the upper and free margins of the two broad ligaments. Each tube, which is of about the size of a goose quill and measures nearly four inches in length, is enveloped closely in peritoneum except over about one sixth of its most dependent surface, where it rests on the areolar tissue in the broad ligament and where the latter constitutes a sort of mesosalpinx. The mucous lining of the Fallopian tube is somewhat plicated longitudinally and is continuous with that of the uterus, but it differs from the latter in that it possesses no glands. Directly underneath the peritoneal covering of the tube there is a small amount of areolar tissue and between the peritoneal covering and the mucous membrane are two delicate layers of muscular fibres—an external or longitudinal and an internal or circular. The blood supply to the Fallopian tube, which is sufficient to meet its ordinary everyday requirements, is derived chiefly through a few small offshoots from the ovarian artery, a vessel which, running tortuously in the broad ligament from the side of the pelvis, devotes its supply of blood chiefly to the ovary. The capillary vessels in the fibrovascular layer of the mucous lining of the tube are apparently constituted like the capillaries of any ordinary mucous corium. Because the blood supply to the Fallopian tube and the substance of the broad ligament is very ordinary, every fetus which attains maturity outside the uterus is enabled to do so in virtue of an accessory supply of blood obtained by the structure in which the fetus had been lodged, contracting adhesions with the omentum, and sometimes with the bowel as well. These adhesions are not associated with any inflammatory reaction but result merely in consequence of the greatly increased vascular activity in the structure harboring the product of conception and the demand of the fetus for an adequate supply of all those materials necessary for its development and growth. The blood supply to the uterus is on a very different footing and is capable of furnishing all the nutriment necessary to meet the requirements of two, three, or even four fetuses.

When a fertilized ovum becomes arrested in the Fallopian tube, it endeavors forthwith to anchor itself by chemiotaxis on that surface of the tube which rests in the substance of the broad ligament, as here alone is it likely to be able to arouse that amount of vascular reaction which is necessary for its immediate requirements. The area of this vascular reaction is not limited but involves more or less markedly the bloodvessels of the entire tube, and if sufficient nutriment is not obtainable from the immediate implantation area, then the oosperm in a definite attempt to safeguard its existence becomes villous over its entire surface. The chorion possesses everywhere the power of throwing out villi, but the product of conception that becomes universally villous is pathological and has become covered all over with villi because it failed in a normal manner to secure for itself that amount of pabulum that it required. So ill fitted, however, are the capillaries of the Fallopian tube to undergo the progressively increasing amount of dilatation that the actively developing product of conception demands, that the process of gestation seldom proceeds far before some of the attenuated capillaries rupture and the hemorrhage that results, not only causes the embryo to perish, but may endanger the life of the mother. It must be remembered that, on account of a more or less prolonged continuance of the patency of the breach in the wall of such enormously dilated capillaries, recurring hemorrhages are likely to take place and sooner or later the blood thus thrown out escapes into the peritoneal cavity by bursting the greatly thinned Fallopian tube. On this account an ectopic gestation seldom proceeds far before it is brought to an abrupt termination and consequently it rarely happens that an extrauterine fetus is so safeguarded as to reach maturity. Out of sixty-three cases of ectopic pregnancy that I have myself dealt with by abdominal section in six only had the fetus attained maturity, and in all of these the infants had died before the mothers came under my observation and in each case the mothers sought advice simply and solely because childbirth had not yet taken place as had been expected.

In my article on the Natural Limit of the Duration of Human Gestation (1) I referred to the fact that although the maternal circulation in the placental area continued active and vigorous, the full time extrauterine fetus does not live on indefinitely in its mother's body but dies without a struggle at a definite and fixed time, unless delivered by the timely intervention of an abdominal section of the mother. Incidentally I may here observe that in all the cases of full time extrauterine pregnancy that I have had to deal with the infants were as well formed and as well nourished as any normal uterine infant could possibly be.

Scientists are well aware that almost daily for many weeks in succession a domestic hen may lay an egg furnished in very definite relative proportions and in exact amounts with all those materials —oxygen excepted—that the chick requires to enable it to complete its development and growth during the incubation period of twenty-one days, and it is most noteworthy that those materials are secreted partly by the ovary but partly also by the oviduct—two distinct and separate structures acting in unity. We know full well that some of the materials found in the egg do not exist in the same chemical state in the blood of the mother but are elaborated and altered by the remarkable powers and processes of the cells which secrete them. The presence of the varied substances in the egg cannot be accounted for by any physical or mechanical laws. Although the nutritional processes connected with the development and growth of the chick take place outside the mother's body and can be observed, we are, strange to say, woefully ignorant of the nature of those chemical changes which the yolk and white of the egg undergo before they are fit to be used by the cells of the embryo itself, and practically all we do know is that they are acted upon and absorbed and transported by itinerant cells which are themselves embryonic.

As to the manner in which the placenta functions, we have at present to confess that our knowledge thereon is extremely meagre and that it has been advanced but little since the days of John and William Hunter—a century and a quarter ago. By a careful study, however, of the conditions obtaining in association with the evolution of the placenta in cases of ectopic pregnancy and in association with the death of the full time extrauterine fetus *in situ*, our knowledge of the actual processes by which the placenta fulfils and carries on its functions may be very materially and reliably augmented.

It will readily been admitted that the nutritional requirements of the embryonic cells for development and growth are very different from those of the maternal cells for maintenance and repair, and that the placenta as the sole intermediary between the embryo and the mother must not only exercise a well regulated selective power but must, by the vital activity of its cells, break up and synthesize many of the substances which it abstracts from the maternal circulation. I am fully convinced that the placenta must carry on its functions much in the same way as the mammary glands during activity carry on theirs.

During embryonic growth, and especially in the early days of embryonic growth, water plays a most important rôle, and it must be evident that the osmotic powers and processes of the cells of the embryo must be very different and very differently regulated from those of the cells of the mother. So, too, the need of the embryo for mineral substances is relatively on a different scale from that of the mother. This applies markedly even in the case of iron. Bunge, who has devoted some attention to this question, says that "in a series of estimations of iron in the total organism of young dogs, cats and rabbits, I have shown that the amount of iron is the highest at birth and that it gradually diminishes afterwards. At least five times more iron is found in the liver of newborn than in that of full grown animals. In the same way the other tissues must possess their store of iron which can be drawn upon to meet the rapid development of the blood." There is, too, on the part of embryonic cells, both vegetable and animal, a remarkable and great demand for fat, and as we find in human milk, which is nature's food for the newborn infant, saturated fatty acids containing six, eight, ten, twelve, and fourteen carbon atoms, fatty acids different altogether from those stored up in the tissues of the mother and drawn eventually into her blood, we are justified in assuming that these same members of the fatty acid series are synthesized in the placenta in the same manner as the mammary glands synthesize them.

It is more than probable, too, that as large quantities of nonnitrogenous food materials are required during the early stages of embryonic growth, the chief carbohydrate used by the embryo is a form of sugar, like lactose, and as this form of sugar does not exist in the maternal blood it will have to be manufactured by the placental cells. Be this, however, as it may, the placenta evolved in association with an extrauterine fetus which attains maturity is in every respect as functionally active and vigorous as any placenta developed normally in the uterus. Structurally the only difference between the two placentæ is that, while the uterine is so related to the uterus as to be shed at the time of parturition, the extrauterine placenta becomes so intimately incorporated with the maternal tissues that it virtually becomes a portion of the mother's body. It is, as a matter of fact, in virtue of this firm union that any extrauterine fetus is enabled to attain maturity and it is on this account, too, that when operating for the removal of a full time extrauterine fetus, even though it is known that the fetus must have been dead for weeks, no attempt should be made to remove the placenta, as the mother is almost certain to die in consequence of the uncontrollable hemorrhage which is certain to result. We must recognize and realize that the placenta which has sufficed to bring to maturity an extrauterine fetus is to be viewed for the time being as a portion of the mother's body and must be left undisturbed to undergo gradual absorption *in situ*, which it does because it has ceased to function. It is noteworthy that in days gone by, before extrauterine pregnancies were dealt with by abdominal section of the mother, the infant and placenta were allowed to disintegrate and undergo absorption, and under such circumstances fetal bones or portions of fetal bones not infrequently were passed by the bowel or bladder.

Now, whether the product of conception is lodged in the uterus or in the Fallopian tube the maternal tissues take no part in the actual production of the placenta itself, which is entirely an embryonic formation. However, as the placenta formed in the uterus has to be shed, the uterine mucosa makes provision for this and keeps on secreting a decidual material which prevents a connective tissue union between the placenta and the uterus. It is truly a somewhat remarkable and inexplicable fact nevertheless, that in a fair percentage of the cases of ectopic pregnancy decidual membrane forms very early in the cavity of the uterus and this decidual membrane, which may be shed as a complete cast of the uterus and with practically no hemorrhage, contains fusiform and epithelial cells but is constituted chiefly of small round cells in a homogeneous matrix. It is no doubt a secretory product formed very much in the same way as the egg shell membrane in the bird's egg is formed.

Regarding the manner of the initial implantation of the product of conception we have no justifiable reason for believing that it differs according to whether it takes place inside or outside the uterus. Time was when it was believed that the oosperm which developed in the uterus became lodged in a specific ovigerous chamber formed by the decidua—the socalled decidua reflexa growing up, around, and over the oosperm and thus shutting it off from the uterine cavity. This dogma which had for centuries retained its sway has, however, quite recently been superseded and there now prevails the belief that the oosperm, by its socalled trophoblast, attacks the mucous membrane of the uterus and either actually devours it or secretes a digestive fluid which dissolves it and that then the oosperm is enabled to insinuate itself into the substance of the mucosa and form therein for itself an ovigerous chamber, the inlet opening becoming sealed over by a structure known as the decidua capsularis.

From a careful scrutiny of facts I am confident that the product of conception which proceeds to develop normally in the uterus neither forms for itself nor has formed for it an ovigerous chamber distinct and separate from the uterine cavity, and that wherever it may proceed to develop it retains in its early days its implantation hold on the maternal tissues simply and solely by chemiotaxis.

A short time ago I had occasion to remove by supravaginal hysterectomy a uterus in an early state of pregnancy. The operation was necessitated on account of a large fibroid growing from the posterior wall of the uterus and so filling the pelvis as to cause retention of the urine. The case is somewhat unusual and is worthy of note. The patient was thirty-five years of age and although she had been married nine years she had never previously been pregnant. At the time of the operation she had gone nineteen days over her usual menstrual period and this was the first and only period she had ever missed. On this account solely I suspected the existence of early uterogestation and was careful during the operation not to disturb the state of the uterus. The uterus, slightly enlarged and presenting the vascular appearances of early pregnancy, looked as though in a plastic state it had been thrown against the large fibroid and had stuck to its anterior surface. There were no other fibroids. The uterus and tumor were removed *en masse* and placed immediately after the operation in preservative fluid. On the following day the specimen was dealt with. It was then remarked that the contracted and hardened uterus had caused a small spherical body, like a small grape, to project at the amputated surface of the uterus—the supravaginal amputation having been effected at about the level of the internal os uteri. On carefully opening the cavity of the uterus the small projecting globular body, which was the product of conception and was quite smooth, over three fourths of its surface was found to be attached to the anterior wall of the uterus by a fanlike *chorion frondosum*. Neither to the naked eye nor under the lens did the surface of the chorion show any evidence that it possessed or ever had possessed a covering derived from any portion of the mucous lining of the uterus; neither was there any sign about the uterine wall that the product of conception had ever been lodged in a special ovigerous chamber, the confines of which it had burst and been extruded from. The chorionic sac was about five-eighths of an inch in diameter.

The embryo which had been developing normally up to the time that the uterus was removed from the mother's body measured in its greatest length 6.5 millimetres. It was closely shrouded in its amnion because there was as yet no amniotic fluid. The sac of the chorion itself was fully distended by a clear albuminous fluid. Here, then, we had a perfectly normal and actively developing product of conception which, according to my method of computation, contained an embryo which was nineteen days old and which product of conception showed not the slightest evidence that it could ever possibly have been located in an ovigerous chamber distinct and separate from the uterine cavity. Moreover, if we scrutinize the development of the bilobed placenta, an occasional occurrence in the human female but a normal occurrence in the case of many monkeys, such as the Cercopithecus sabaeus and the Macacas cymologus, in which it is asserted that an ovigerous chamber is formed by the trophoblast in exactly the same manner as it is formed in the human female, and take into consideration too the occasional occurrence in women of that somewhat remarkable and troublesome condition known as placenta prævia, it is absolutely impossible to believe that the oosperm forms for itself a specific chamber in the uterine mucosa. In the case of monkeys, where the placenta is bilobed, the two lobes more or less discoid in shape and of about the same size are usually situated one on the anterior and the other on the posterior wall of the uterus. At the fundus and sides of the uterus the two lobes are separated from each other by nonplacental smooth parts of the chorion. The umbilical vessels join the fetal surface of one placenta and the interplacental vascular communication is maintained by tortuous vessels traversing the smooth nonplacental portions of the chorion.

When Turner's communication on the Placentation of the Apes appeared (2) it was evident that that distinguished anatomist, in common with such scientists as Breschet, Owen, and Rolleston, accepted the tenet that the product of conception which produced a bilobed placenta was developed in an ovigerous chamber distinct and separate from the cavity of the uterus. With scientists as with other persons the wish is sometimes father to the thought and here it would seem we have a case in point, for gradually the belief is being abandoned that the bilobed placenta in the monkey is developed in an ovigerous chamber shut off from the uterine cavity. What is true of the bilobed placenta in the monkey is likewise true of the bilobed placenta evolved at times in association with the human product of conception. There can, as a matter of fact, be little doubt that the bilobed placenta as developed either in the human female or in the monkey is evolved in the uterine cavity itself, just as the cotyledonary and annular placentæ are in some of the lower mammals. This obtains, too, in the case of the well formed discoid placenta which is so situated in the human female occasionally as to constitute the condition known as placenta prævia, since it is inconceivable that a placenta evolved in a chamber lodged in the uterine mucosa in the immediate neighborhood of the internal os could ever be anything but misshapen.

In coming to a conclusion on this important and interesting scientific question it must be remembered that those who cling still to the dogma that the human product of conception develops in a specific ovigerous chamber assert that when the blood supply to the socalled decidua reflexa or capsularis is reduced the villi of the chorion in relation to that structure degenerate and being compressed between the chorion and the opposed reflexa now rapidly disappear. Or take again the fact that during uterogestation it not infrequently happens that as early as fourteen days after the first menstrual period is missed external hemorrhage may be noted in consequence of the rupture of one or more ill conditioned or badly supported capillary sinuses in the decidua serotina or placentalis area, and even although this hemorrhage may persist and be troublesome for a greater or less length of time the pregnancy may nevertheless proceed and the fetus reach maturity. Now it is quite clear that if in such a case the product of conception were lodged in a special chamber in the mucosa of the uterus, the blood escaping from ruptured vessels within its walls could only make its appearance externally by bursting the wall of the said ovigerous chamber, and it is inconceivable that this could possibly take place without the product of conception being at the same time destroyed. It is alleged, too, that as the placenta in the ovigerous chamber develops and the embryo grows the decidua reflexa or capsularis is stripped from the musculature of the uterus and thrust against the decidua vera of the opposite side and that these two veræ fuse about the fifth month and thereafter the reflexa or capsularis atrophies. Under such circumstances it must also be quite evident that blood emanating from the placental site and appearing externally during the first five months of pregnancy could only do so by breaking the decidua either directly or indirectly after tunnelling beneath it for a greater or less distance, but we have no evidence clinically or pathologically that the occurrence of external hemorrhage during the early months of pregnancy is ever associated with either of those events. Confronted, therefore, with facts of the aforesaid character it is imperative that we should now abandon the idea that the human oosperm ever devours or attacks the living formed tissues of its mother in order that it may form for itself a special gestation chamber. We can consequently only view as erroneous such a statement as "if the developing ovum be arrested in the Fallopian tube, the syncytium owing to the extreme thinness of the lining membrane quickly eats its way into and through the wall of the tube" (3).

Taking all facts into consideration I think there can be but little doubt that early implantation of the human product of conception, wherever it takes place, is effected by chemiotaxis. It must also be clearly understood that the fertilized ovum which comes to arrest and proceeds to develop in the Fallopian tube is enabled to progress and produce a mature fetus because the placenta becomes virtually a part of the mother's body and because the growing product of conception in its entirety insinuates itself into the substance of the broad ligament separating its constituent parts just as a cyst does which originates in the hilum of a more or less sessile ovary.

In my communication, The Natural Limit of the Duration of Human Gestation, already referred to, I drew attention to the fact that gestation, in the case of every woman who conceives, begins at a definite and fixed time and that that definite and fixed time is two days before the date when the first missed period was expected to make its appearance, and I instanced as a most valuable aid to the settlement of the very vexed question of the duration of human gestation the further fact that the full time extrauterine fetus dies at a definite and fixed time unless its timely delivery is effected by an abdominal section of the mother. I observed, moreover, that the infant died without a struggle and that the mother herself was wholly unaware of the probable time when her infant perished. Now I have no hesitation in asserting that the full time extrauterine fetus dies paralyzed from lack of oxygen and lack of mineral substances, because the limit of the duration of the functioning activity of the placenta has been reached and the cells concerned thereto have lost their selective powers. This abrupt termination of the life of the fetus is clearly due to oxygen starvation and mineral hunger, because as I have already remarked the full time extrauterine fetus at the time of its natural death is as well developed, as well formed, and as well nourished as any normal uterine fetus is at the time of its birth. Here, then, we have irrefutable proof that through the mediation of the placenta the gaseous interchange between the maternal and fetal circulations and the passage of all the other nutrients that the fetus requires for its growth and development are determined and governed by the vital quantitive selective powers of specific placental cells and are not effected purely and simply in a physical or mechanical manner as is generally believed. As a matter of fact, we know that the maternal circulation in the region of the placenta in the case of a full time extrauterine fetus continues vigorous and active for a greater or less length of time after the fetus dies and unless the fetal circulation fails in the manner I have indicated there is no apparent reason why the full time extrauterine fetus, instead of perishing at the definite and fixed time it does, should not live, one is tempted to say, indefinitely. I may observe incidentally that stillbirths due to oxygen starvation are of fairly frequent occurrence but the reactionary lowering of the vascular activity in the uterus associated therewith usually so impairs the irritability and sensitivity of the uterus that parturition may be delayed for days after the infant has perished.

It might of course be thought that the death of the full time extrauterine fetus *in situ* could reasonably be attributed to the advancement of those changes in the circulatory structures of the fetus which take place in anticipation of birth, but we have no evidence that the death is in any way connected with or dependent upon those changes. It is besides universally admitted that the alteration in the course of the fetal circulation is determined by the first inflation of the lungs with atmospheric air and we must recall that it is on this account that the infant born weeks before those changes in the circulatory structures are completed is enabled, not only to survive its birth, but to continue its independent existence.

Without the maternal and fetal bloods commingling in the full time extrauterine placenta we have become aware that the full time extrauterine fetus is enabled to attain maturity only if the placenta becomes virtually a portion of the mother's body, and from a careful scrutiny of facts it must be very evident that the death of the full time extrauterine infant at a definite and fixed time can only be due to the placenta as sole intermediary between the mother and infant losing at a definite and fixed time its functioning powers. In other words, the passage of all those materials which are requisite and necessary to enable the fetus to complete its development and growth, no matter where the fetus may be located, is determined and regulated by the selective powers of a vital character exercised by certain placental cells. The placenta, in fact, plays a rôle of an internal secretory organ functioning very much in the same manner as the mammary gland in a state of activity.

Supporters of the mechanical theory of the functioning of the placenta allege that by the physical laws of diffusion filtration and osmosis all the nutrient processes occurring through the placenta can be understood and explained. I, on the contrary, maintain that even the passage of the diffusible mineral substances which the fetus requires cannot be accounted for by physical laws, because the specific needs of the embryo for growth and development are very different from the nutrient needs of the mother, and because the relative proportions of the mineral and other substances circulating in the mother's blood are very different from the relative proportions which the placenta is required to furnish for the development and growth of the fetus.

The mere fact that certain substances capable of filtration when thrown into the blood of the mother pass into the circulation of the fetus, is no criterion, but a careful study of the conditions as a whole as they obtain in the case of the full time extrauterine fetus in its relation to its placenta is of the greatest scientific value.

Primary Sarcoma of the Spleen

By HARRY C. W. S. DE BRUN, M. D.,
New York.

At various intervals a case of splenic sarcoma creeps into literature and surgeons forget it until their minds are again refreshed with a new case. In the past few years I am unable to find in literature the report of an authentic primary sarcomatous spleen.

As a primary condition the spleen is rarely attacked by tumor growths and as a matter of fact secondarily it is nearly equally as rarely the seat of metastases of any great size. It does take place, however, usually by extension from the stomach. This can, of course, be readily explained by its buried position in the abdominal cavity, being protected by ribs, stomach, splenic flexure of colon, gastrosplenic omentum, phrenocolic and lienorenal ligaments and other peritoneal folds. It is quite free of mechanical irritations. The most plausible mode of infection, if sarcoma be an infection, is through its unusual blood supply, i. e., the endothelium of the capillary network coming into direct contact with the splenic pulp. I feel, however, that irritations do take place in people whose occupations cause a great deal of left sided bending and stooping or leaning to the left side and especially in persons whose spleens are somewhat enlarged by previous disease. On the other hand, when it attacks women I feel that an ill fitting corset may irritate an already enlarged spleen.

By far the most common form is the lymphosarcoma having its origin in the lymphoid structures. Other types are fibrosarcoma originating from the capsule and trabeculæ, large round cell sarcoma of endothelial origin, cavernous angiosarcoma of lymph vessel and cavity origin. I have been unable to find a case record of such an occurrence.

Weichselbaum (2) reported two cases, one a fibrosarcoma and the second a large round cell sarcoma both in young men. Council (3) reported thirty-seven cases of which seven were still living following sixteen splenectomies; three died after operation, five recurred, and one patient was lost track of. Others reporting cases are: Jepson and Albert (cured case); Willy Meyer (patient died); the journal (4) reports twenty-four undoubted cases of sarcoma of the spleen, eleven found at postmortem; of the thirteen splenectomies four patients died at operation, four of recurrence, one lost track of and two cured. Cohen and Reisman (5) had a case lasting six months without operation. Billroth had a case, in a woman of forty-three, in which he did a splenectomy. Fritsch (6) operated on a woman of thirty-one who lived a year in poor condition after extirpation. De Ritis, Sancereaux, Trelot and Clark and Whitney have reported cases.

The patients usually come in complaining of having had pain in the back several weeks, gradually getting worse. They complain of gastric indigestion and the presence of a gradually increasing mass in the abdomen, a growing palor and weakness.

The diagnostician must rule out the following most common conditions simulating malignancy: In the splenic type of Hodgkin's disease, when no other glands are involved an exploratory incision is essential. Hypernephroma and renal tuberculosis may be diagnosed by cystoscopic examination with urethral catheterization and the x ray. The chronicity of Banti's disease and the early secondary anemia make the diagnosis. Cyanosis, extraordinary increase of red blood cells and chronicity of the disease rule out Vaquez's disease. History of onset and jaundice—conjunctival lesions—enlarged liver point to family types of splenomegaly. Infarct and abscess of the spleen occur in the course of septicemia or pyemia and endocarditis or other febrile disease. In acute swelling of the spleen we find a history of a primary condition. Chronic swelling of spleen reveals a history of cirrhosis of the liver, chronic heart disease, leucemia and paludism.

In angioma of the spleen other organs are usually involved, especially the liver, skin, and omentum. The liver is first attacked. There is pulsation and murmurs over the organ. An exploratory operation is at times essential for a positive diagnosis for the masses of vessels often simulate metastasis.

In tuberculosis of the spleen an insidious onset and the presence of other foci in neighboring viscera will distinguish the condition. X ray, cystoscopic examination and bacteriological examinations aid materially in the diagnosis.

In syphilitic infiltration of the spleen the history and a positive Wassermann are valuable but one must not lose sight of the possibility of both conditions being present. The course of actinomycosis of the spleen and its similarity to abscess without a known possible cause should be suspicious. Exploratory operation confirms the diagnosis.

In malaria the onset, blood smears, clinical course and progress under treatment will rule out other similar conditions.

In hemolytic jaundice intermittent or remittent jaundice will rule out a malignant spleen unless both conditions are present. The finding of urobilin in the stool up to four gms., bile in the urine and increased fragility are important findings.

In tropical splenomegaly the protozoa from the spleen puncture will be found and it occurs in tropics and subtropics.

Uteroovarian disease may be ruled out by the history of the case and bimanual examination.

With the present day use of pneumoperitoneum in x ray diagnosis the various organs involved are more easily distinguished.

TREATMENT.

As yet the x ray and radium have not been given a sufficient trial, on account of the lack of material, to say that relief is given or that the process has been arrested, so I am of the opinion that the method of choice is surgical intervention. One should be extremely careful in the manipulation of the spleen both before and after operation. When possible cautery should be utilized. Adhesions should be broken up carefully. Most often there has been an adhesive process to the stomach and diaphragm and if superficial the bleeding points should be gone over with the cautery. The patient should be given deep x ray therapy postoperatively and care should be given to the first sign of recurrence keeping in mind the routes of spreading; first by direct extension usually attacking the stomach, diaphragm and peritoneum. Secondly, through the lymph channels to glands and other viscera. And thirdly through the blood stream especially to the heart and lungs.

PROGNOSIS.

As the patient is usually seen late in the course of the disease the hope of recovery is slight. When the cases have reached the surgeon early good results have been seen in the few cases reported. It is to be hoped that with the education of the public to consult physicians early, and with the wide increase and the advances in diagnosis I feel that the patients will come to operation and radiation early and the condition will not be looked upon as hopeless as heretofore.

Case I.—Miss B. L., aged twenty-two, a saleswoman, was referred to me for examination August 16, 1921. She complained of pain in the left side radiating to the back. It was cramplike in character and worse at night. She had had this pain since an attack of dry pleurisy three months previously which was treated by strapping. Two weeks prior to my seeing her she had noticed a mass in the left abdomen which was gradually getting larger. She suffered from gastric indigestion and constipation since the mass became apparent.

The patient had had measles, chickenpox and otitis media in early childhood, at nineteen a peritonsillar abscess and at twenty a fracture of the left tibia. The menstrual history was quite normal except for occasional attacks of leucorrhea. At twenty she noticed a swelling of the thyroid gland at the time of her period but it disappeared under x ray treatment.

Dr. Alfred Herzfeld and myself elicited the following physical signs: The patient was a well developed and well nourished girl with moderate pallor. The skin was dry and cold. The head and neck were normal. The heart was pushed up and rotated forward, but there were no adventitious sounds. There was tactile fremitus or rather a crepitation over the base of the left lung. There was dullness to flatness at the left base posteriorly continuous with a mass in the left abdomen.

On inspection there was a perceptible swelling over the left side of the abdomen reaching from the costal margin to the umbilicus. A slight movement with respiration was noted. The mass was firm and smooth with a sharply defined internal border extending from under the ribs in the left hypochondrium downward and inward to just below the umbilicus. It was more or less fixed, moving slightly with respiration. The right kidney was palpable and moved with respiration. On filling the stomach with gas I found that there was a tendency for it to lay on the right side of the abdomen. There was crepitation over the tumor mass probably due to a perisplenitis. The liver was not palpable. The extremities were normal, reflexes normal. The rectal examination was negative.

The patient was admitted to the Lenox Hill Hospital and came in on the service of Dr. Martin Rehling, who was chief of the surgical service at that time. After careful examination, review of findings and consultation with the medical men, it was decided to operate. Dr. Rehling's preoperative diagnosis favored a malignancy.

Dr. Otto Hensel's report (medical service) : "I was unable to find any lesion except a great enlargement of the spleen. The diagnosis rested between Gaucher's disease, Banti's disease and the splenic type of Hodgkin's disease, with the last least probable. There is a possibility of primary tumor; the rapid growth and the deformity of the chest wall speak for this." Dr. Hensel suggested an x ray for glands, urine examined for urobilin, blood examination to determine the resistence of leucocytes and the presence of reticulated cells and bile in the serum. He also advised exploratory puncture of the organ. The family history was investigated but no similar conditions were present. Dr. Hensel advised finally splenectomy and irradiation.

For two weeks prior to operation the temperature ran from 98.6° to 104°, usually higher in the afternoon. Two days before the operation it remained persistently high and patient suffered from epistaxis. The pulse from 80 to 120. Respiration, 18 to 24. Up to the day of operation she was given a soft diet with daily soap enema. Blood pressure was 98/50.

The urine was examined daily before operation; acid, specific gravity 1.014 to 1.027; clear light amber; albumin: 1-3 plus with occasional hyalin and granular casts up to 2 plus. Red blood cells, 2-3 plus, white, 3 plus, epithelial, 2 plus, no urobilin.

Blood: hemoglobin, 60-80 per cent. (complete rest in hospital increased the hemoglobin). Red blood cells, 4,600,000-4,800,000; white blood cells, 10,500-15,400; polymorphonuclear, 59-69 per cent.; eosinophiles, from nine per cent. two weeks before operation to three per cent. on day of operation (September 1, 1921). Small lymphocytes, 24-29 per cent.; large lymphocytes, 3-8 per cent.; no reticulated cells; no parasites. The Widal was negative, culture negative, Wassermann negative. The gastric contents were normal. The stool was negative for ova, parasites and blood at several examinations.

A preoperative diagnosis of primary sarcoma of the spleen or cystic spleen was made.

OPERATION.

September 1, 1921, two doses scopolamine (,02), novocaine ½ per cent. (Dr. Rehling). A left mid rectus incision was made from the costal arch to one and a half inches below the umbilicus. (Gas, oxygen and ether (thirty c. c.) anesthesia was started on opening the peritoneum.) It was found that the uterus was infantile, tubes and ovaries were normal. There was no mass in the appendix region. The liver was smooth. The spleen was immense, presenting a smooth surface but several large elevations were felt. The organ extended upward and backward and there were a few adhesions of the dome of the diaphragm and at the left of the spinal column. As the spleen was so tremendously enlarged it was impossible to bring the organ to the wound so two auxiliary incisions were made; one to the xiphoid and the other a transverse to the left for two and a half inches. The spleen was now dislodged and hot packs applied to the oozing surfaces under the diaphragm. The spleen was completely loosened from above downward and several friable areas were torn through at the vertebral column and the stomach. The pedicle was isolated and tied and spleen removed. As there were infiltration processes at the fundus of the stomach and the vertebral column a resection of the stomach was not attempted. As there was little oozing the wound was closed without drainage with superficial and deep chronic sutures. A row of heavy silk sutures was laid to give support to the abdominal wound. In spite of the fact that the patient was in good condition a transfusion was performed with 500 c. c. blood (citrate method). The whole operation took one hour and fifteen minutes. On August 25, 1921, stereoröntgenographic examination revealed a cloudiness at both apices more marked on the right side. Both hilus shadows were prominent. No evidence of glandular involvement was seen. September 27th, an area of density involving the lower left lobe and obscuring the left diaphragm from the fourth rib to the base was seen.

After a pneumoperitoneum röntgenographic examination revealed a large dense shadow occupying the left hypochondrium and left lumbar regions. Two distinct shadows were noted, the upper corresponding to the spleen was of lesser density. The lower overlapped the lower shadow of spleen. This lower shadow corresponded with that of a large movable kidney with the cortex apparently resting against the vertebral column and the lower pole on a level with the lower border of the fourth lumbar vertebra. There was ptosis and hypertrophy of the right kidney.

With these findings it was deemed wise to x ray the urogenital tract in spite of the fact that the surgical staff did not think the kidney was involved.

August 29, 1921, cystoscopy showed the bladder and both ureteral openings to be normal. The catheters entered easily and brought clear urine. Indigo carmine injected intramuscularly was excreted in eleven minutes (both kidneys). Sodium iodide injected: Left kidney 20 c. c., right kidney 5 c. c. Stereoröntgenograms after the passage of opaque catheters and instillation of opaque fluid into both kidney pelves revealed a ptosis of both organs more marked on the left side. The left pelvis was larger. The superior calices were slightly enlarged with slight irregularities noted. No evidence of inferior calices was noted. The middle and inferior calices appeared normal, but the minor were not visualized. A distinct kinking of the left ureter just below the pelvis was noted. A large area of density was noted on the left side extending from the left diaphragm to the crest of the ileum. This, no doubt, was an enlargement of the spleen.

Examination on October 16th, two days before her death, showed her delirious from inanition. Eye grounds were clear. There were masses of large glands throughout the abdomen and chest, and the liver was large and nodular. Glands were also palpable in the cervical inguinal and axillary regions. The temperature rose to 106° and she died on October 18th, forty-nine days after operation.

On return from the operating room the pulse was 120, respiration 24, and the patient's condition was fair. She did not suffer from postoperative nausea or vomiting. Shock blocks No. 3 were used at the foot of the bed for three days. The extremities were bandaged; a Murphy drip was given continuously for three days. Hypodermoclysis, 1,000 c. c. twice daily for the first two days. The patient complained of cramps at various intervals. On the third day colonic irrigations were given at first. A dark brown fluid and a great deal of flatus was expelled. She was quite comfortable on the fourth day, and improvement was then rapid as far as pain in the back and cramps were concerned. Pain was entirely absent on the fifth day. After operation the temperature rose to 105.2° on the morning of the second day and gradually fell to normal on the fifth day. After this the temperature again arose at various intervals to 101.6°. The pulse after operation rose from 96 to 164 on the second day but gradually came down to normal limits. Respiration varied from 24 to 32.

Medication: Codeine was given. Beginning on the ninth day tincture of digitalis was given. Eserin salicylate at intervals was required. Chloral and bromides at intervals and cascara were also used.

The sutures were removed on the eleventh day and the wound condition was good. On the thirtieth day after operation physical examination disclosed fluid in the left base which was verified by the x ray. A mass was palpable in the epigastrium which was tender and movable. The heart was now normal in size, shape and position but there was a soft blowing systolic murmur at the apex transmitted to the scapular region. The patient was discharged September 30th (thirty days after operation) at her request. At this time she complained of severe pains in the back but not as severe as on admission. She also was disturbed with nausea and vomiting at intake of any food. She was extremely weak and cyanosed. Her bowels were constipated and she would hiccough for hours at a time (irritative). She gradually became worse and was kept under narcotics continually.

PATHOLOGICAL REPORT.

The specimen consisted of a large spleen measuring twenty by eleven cm. and weighing 1090 gms. which was incised longitudinally. The surface was irregularly nodular, the nodules involving the entire surface area except small portions at both poles and the anterior and posterior borders. These nodules were somewhat denser in consistency than the normal splenic tissue and in the areas where there was no splenic tissue intervening they appear yellowish white in color. On the external surface there was an area of hemorrhage beneath the capsule and a raised, dense, yellowish white irregular nodule measuring two by three cm. The gastric surface showed evidence of forcible separation and tearing of the spleen tissue. On section the splenic tissue was seen to be almost completely replaced except for a narrow vein about the periphery by nodular masses of yellowish white tissue which bulged from the cut surface and were more or less incompletely separated by prolongations of splenic tissue extending in from the periphery. In some areas these masses reached the capsule.

Examination of sections of the tumor showed areas to consist of closely packed cells showing no definite structure. The stroma in these areas was scanty or indistinguishable. In other areas the tumor was traversed by delicate or thicker fibrous trabeculæ which in places divided the cells into ill defined alveoli and columns. The tumor cells were for the most part round in shape and of moderate size, being somewhat larger than the large mononuclear leucocytes. They contained a relatively large nucleus, the chromatin of which was arranged in small dots. Most of the cells possessed but a single nucleus, although here and there were multinucleated cells. Mitotic figures were observed in many of the cells. The tumor was well vascularized and showed scattered areas of hemorrhage and necrosis. (Report from the laboratories of the Lenox Hill Hospital.) A pathological diagnosis of sarcoma of the spleen was made (Dr. Priest).

There was a question as to whether the enlarged thyroid was the seat of a sarcomatous lesion, but I feel that inasmuch as she had had this enlargement for several years at the time of her menstrual period, we can rule out that possibility. The intense pain that the patient complained of was probably due to the stretching of the capsule with the vessels and nerves. The first symptoms of recurrence were referable to the gastrointestinal tract. The palpable mass in the epigastrium was probably in the cardiac end of the stomach due to a direct extension by contact at time of operation. The process then followed the lymphatic system and finally through the blood stream which was rather unusual, inasmuch as the circulation is directly through the spleen and liver. With such a rapid spread it is remarkable that the brain escaped metastases.

Giffin (7), of the Mayo Clinic, believes that when a spleen is enlarged and causing pressure symptoms it should be removed. In this case the pain was intense and this alone made its removal justifiable. Also its absence reduces the amount of diseased blood to the liver and relieves the secondary anemia to a certain extent. Giffin has stated the hospital mortality of 245 splenectomies as 10.6 per cent. plus but this is of all varieties of splenomegaly and also some patients died shortly afterward. Naturally in malignancy the mortality is bound to be higher. It is higher in large adherent spleens and where hemorrhage is likely to occur. In the Mayo series mortality was lower in hemolytic jaundice and myelogenous leucemia and high in splenic anemia where the spleen is large and fibrous with the presence of perisplenitis, engorged thrombotic vessels and a difficult operation.

It is to be hoped that with the high development of deep x ray therapy the surgeon's work may be enhanced in the treatment of malignant tumors.

Cell Ionization and Its Relation to Malignant Neoplasms*

By DONALD C. A. BUTTS, M.D.,
Philadelphia.

The etiology of malignant growths remains the great question before us, the problem which the tremendous amount of investigation in this field still leaves unsolved. The histological picture of malignant neoplasms is well recognized, that the cells comprising such new growths are apparently normal cells which have broken down their supporting membrane and proliferated in an ungoverned manner is the generally accepted belief of most oncologists.

With this condition established and recognized we are forced to ask the following questions: What change in the body, locality, or functioning of a particular organ has brought about such an arrangement of the cells which the pathologist has called carcinoma; what is the factor which has supplied to the formerly normal cells this necessary stimulation for such a histological arrangement and atypical proliferation?

Weighing with care the many inadequate theories emanating from years of research into the etiology of malignancy, has led me to bring forth a hypothesis, that of cell ionization, which seems to answer the principal, pertinent questions in the fields of its pathology and physiological chemistry. Cell ionization here signifies the electric control and direction of cellular metabolism dependent upon the presence of unbalanced positive or negative electric charges in the cellular elements of the tissues involved.

The action of enzymes as applied and related to our subject shall first be considered as it is upon such an action that this hypothesis is based.

ENZYMES OR FERMENTS.

These are primarily catalytic agents, hastening chemical changes without undergoing any change in themselves, nor do they enter into the resultant combination. The reaction of the medium in which the enzymes display their activity is very important; some acting only in an acid medium, others in alkaline or neutral media. The mode of action of the enzyme is specific, i. e., fat splitting enzymes act only upon fats, diastases only upon carbohydrates, and proteolytic enzymes upon albumins. In this paper the enzyme will be regarded as an electrochemical catalytic agent, whose chemical action is exerted by the charge which it carries, and will be considered as a chemical agent composed entirely of positive or negatively charged particles which exert their catalytic influence by the liberation of such particles.

ANTIENZYMES.

Of these socalled antienzymes very little is known and they will be regarded here as chemical agents which influence the action of the enzymes by exerting upon the enzyme or the cell the opposite charge of electricity. Thus if the enzyme is one which acts as a catalyst by the liberation of positively charged particles, the antienzyme will possess a negative charge, and vice versa. In consideration of malignant neoplasms where there exists a more or less characteristic arrangement of the cells, together with accompanying symptoms within the body, it is reasonable to believe that there has occurred within the individual cells some definite alteration before this deviation from the normal occurs and the neoplasm develops. Let us consider at this point some of the conditions that exist in the presence of malignant tumors.

HISTOLOGICAL CONSIDERATIONS.

Upon histological examination of sections for research and diagnosis, we find the most striking and differentiating morphological feature in the study of carcinoma, of atypical proliferation of the epithelium composing it, and from which it was derived. Study has shown us that the parenchymal cells of a carcinoma are all descendants of the cells which gave rise to the neoplasm although there may exist a great diversity of the cells composing such tumors, depending upon pressure, nutrition and functional performance.

CHEMICAL CONSIDERATION.

Urinary changes.—Although no definite diagnosis can be made upon chemical examination of the secretions and body fluids, various workers have found the following changes in the urine in a large percentage of cases: increase in colloidal nitrogen, xanthine, oxyproteic acid, urinary ammonia, urobilin, aminoacid nitrogen, and unoxidized sulphur, while a decrease in urea has been reported by various workers.

Blood changes.—Accompanying carcinoma there usually exists a marked cachexia and anemia, reduction in number of erythrocytes, low hemoglobin index, distinct leucocytosis and greatly diminished alkalescence. Elsberg found that normal red cells injected beneath the skin of persons suffering from carcinoma were rapidly hemolyzed, producing a distinct and characteristic discoloration of the skin. Greene has demonstrated an increase in the nonprotein nitrogen together with an increase of nonoxidized sulphur in the blood of cancer patients.

Changes in gastric content.—Fragments of carcinoma are occasionally found in the stomach washings which, if occurring in solid masses with large nuclei and suitably stained, may be used for diagnostic purposes. However, this consideration is of secondary importance in comparison with other changes occurring in a high percentage of cases of carcinoma of the stomach and intestines. Hypochlorhydria (where the amount of hydrochloric acid is low) or achlorhydria (absence of hydrochloric acid) are very often associated with carcinoma of the stomach. Large amounts of lactic acid in the stomach contents are suggestive of carcinoma.

Before entering into the chemistry involved let us discuss briefly the fundamental composition and functions of the cell components, i. e., nucleus and protoplasm.

The nucleus.—The nucleus, usually occupying a central position in the cell, controls metabolic activities and during mitosis transmits characteristic features (heredity). It consists of a network (chromatin); a semifluid substance which fills in the meshes of the chromatin (achromatin); and a distinct membrane or wall. The chromatin chemically consists of nucleic acid and a basic substance, always some member of the simple proteins, which protein differs, however, in every kind of cell.

---

*From the Division of Laboratories, Pennsylvania Department of Health.

The protoplasm.—Protoplasm is a viscid colloidal substance of neutral reaction. Chemically it consists of approximately two thirds water, inorganic salts of calcium, potassium, sodium, phosphorus and oxygen (free or combined). Physically the protoplasm consists of colloids, either liquid (sol), or semisolid (gel) and crystalloids which are electrolytes (bases, acids and salts) or nonelectrolytes (urea, sugar).

The vital spark.—The number of times the question of the origin of the vital spark has arisen is innumerable, yet today we must admit that the answer still remains one of the great mysteries of modern science. With our present knowledge of physical chemistry we know that throughout the entire body there are a series of chemical reactions going on continually and alterations in any one of these accompanying disease manifests itself as diagnostic symptoms for that particular pathological condition. It must also be remembered that these reactions cannot take place without ionization and dissociation of the molecules composing the agents involved. Knowing that our bodies are composed primarily of cells, does it not seem reasonable to believe that any agent disturbing the equilibrium and normal socalled habit chemistry of these cells must be of electrical nature?

It is selfevident that when the normal metabolism or habit chemistry of cells has been disturbed, in so doing they have acquired new structures and functions. It is logical to believe that the necessary stimulus to bring about this change is due in part to a source acting much in the same manner as an enzyme (catalytic agent) and which action is due to the possession of positively charged particles or ions. This electrical stimulus once supplied and the chemical alteration brought about, the cells acquire a new and totally different habit chemistry and continue to grow in this new environment until the source of disturbance is entirely removed or until the normal electric equilibrium is supplied to the original cells (x ray or radium) and normal metabolism is restored. The original stimulus may be due to many sources, all acting in the same manner in a greater or lesser degree, thus determining the rate at which the neoplasm manifests itself.

It has been demonstrated that the action of x ray and radium radiation is upon the cell nucleus (especially upon the dividing cell). A sufficient number of cases of carcinoma developing among the early radiologists warrants an example for the following explanation.

Regardless of the prevailing explanations of the action of radioactive agents, I believe that carcinomata developing among the earlier radiologists was due to the positive rays from the röntgen tube or to the alpha particles of radium which are both electropositive in their action. With the present methods of protection such rays are screened off allowing only the x ray or gamma radiation to be liberated, both of which are light rays having the capacity to break up the atom in their passage through it, liberating negatively charged ionic particles. I believe that such electronegative agents are capable of rehabilitating the normal electrochemical union within the cell nucleus. Due to the short wave length of the positive particles of the röntgen tube and radium, the operator and not the patient was exposed to such an action, resulting in cancer. It does not seem logical to the writer that it was the intense action of x ray and gamma radiation that resulted in cell death with subsequent development of carcinoma. Considering that such an explanation is true and the cells are killed by this intensified action, then how do we account for the predominating characteristic demonstrated in cancer, that of reproduction (cell life). Surely dead cells cannot reproduce. It is obvious that such cases arising among radiologists was not due to a destructive process but rather to one of stimulation which I believe is the action of the electropositive particles, which with great care are now screened off.

Let us grant that x ray and gamma radiation are destructive to all chemical functions of the cell, eliminating such functions and leaving only one property of cell life, propagation. With this condition established, it is readily seen that the life cycle is, through necessity, very much shortened, therefore we could expect a more rapid cell reproduction, which condition does exist in carcinomata, and under its influence the cell acquires and manifests an entirly new and different habit chemistry with its sole property of proliferation, with subsequent infiltration. The functions of cell life are under the influence of such electrical charges, eliminated according to their stability, reproduction being the most stable is the last eliminated.

Where traumatism is considered the etiological factor, we have most probably the same condition in a much modified form, and the most logical explanation seems to be that suggested by Dr. John L. Laird, director of the Pennsylvania State Department of Health Laboratories. Dr. Laird's explanation is that through a disturbance of the trophic nerves, which are supposed to regulate to a great extent the metabolism of the cells, a positive charge is supplied to or exerted upon the cells, thus disturbing their electrochemical union with the subsequent formation of the neoplasm.

Another interesting example is demonstrated in the localities where cancer is most prone to develop. Thus where the reaction is naturally acid (stomach and colon) we have a far greater percentage of cases occurring than where it is alkaline, example, the duodenum.

In consideration of the suggestion herewith presented, let us consider one cell becoming cancergenetic rather than the gross pathology of malignant neoplasms. Hence our first consideration will be that of a normal epithelial cell, working under normal conditions and endowed with its normal metabolism, being continually acted upon by a positive charge, developing into the electrochemically typical cancer cell.

When we consider the physical chemistry of the cell we are forced into consideration of the chemistry of life, inasmuch as our bodies are composed of nothing more nor less than groups of such cells, each, under normal conditions, working in harmony with its neighbor. Although these cells may differ from one another in structure (chemical and histological) and in functions, yet each cell, or group of cells, has its definite and well defined duties to perform.

Cells are endowed with the properties which differentiate the living from the lifeless, i. e., movement, growth, reproduction, respiration and irritability. Under normal conditions these properties form a complete cycle resulting in development and growth of the body, each organ and part being possessed with definite form, structure and duties.

The property of reproduction being of primary importance in consideration of our problem, let us theorize the influence of a positive electrical charge upon cell division. Due to the limitations of space the scheme of amitosis (direct cell division) and mitosis (indirect cell division) will not be described in this paper.

PROLIFERATION AND INFILTRATION.

All oncologists know that the predominating and, with comparatively few exceptions, the only property of cells composing carcinomata is that of proliferation with subsequent infiltration.

Let us consider at this point a group of cells, normal in every respect, being slowly acted upon by an exerting force (positive electrical charge), which would cause changes similar in every detail to those demonstrated in the first stages of karyokinesis. The cell, once stimulated, completes its cycle of division and forms daughter cells, according to the scheme of mitosis, which cells are identical with the mother cell. The force, still exerting its influence, eliminates the period of rest usually following cell division and the daughter cells just formed are immediately compelled to undergo division. Thus it is easily seen that as long as a positive charge exists and stimulating mitosis, that within a comparatively short time we would have a tremendous excess of cells, steadily and rapidly pushing forward, breaking down all bounds of normal retention and growth with the subsequent formation of the neoplasm and infiltration of subjacent tissues.

Now with the continuance of the slow acting positive charge some of the foundation cells acquire a positive charge and act as a nucleus and source of stimulation for the adjacent newly formed cells. The original source of stimulation (traumatism, nerve control, or any condition exerting positive electrical stimulation) acting in connection with the cells in which I believe the normal electrical balance is disturbed and now exert an electropositive reaction, exhausts to some extent their property of proliferation and we get spreading degenerative changes accompanying advanced stages of the disease, that is, after the formation of the neoplasm.

Placing cell metabolism upon the foundation followed throughout this paper (electrochemical) I shall attempt at this point to explain two conditions very frequently observed accompanying advanced stages of carcinoma. Whether or not this bears any true relation to our problem, it at least offers a logical explanation to the conditions under consideration.

The nucleic acid of the normal cell nucleus when functioning properly is electronegative in reaction. The cell receives its nourishment and oxygen from the blood with which it enters into an electrochemical union due to the oxyhemoglobin of the blood, which is electropositive in reaction. Thus under normal conditions we have a direct and active ionization and dissociation of the molecules of the two elements (nucleic acid, electronegative; oxyhemoglobin, electropositive) resulting in the supplying of the proper nourishment to the cell and the breaking up of the oxyhemoglobin with the subsequent liberation of the oxygen, necessary for proper oxidation changes within the cell.

In cancer, however, where both elements (nucleus and oxyhemoglobin) are believed to be electropositive, proper ionization, dissociation, and electrochemical union of the two elements is impossible, with the result that the cells do not receive their proper nourishment and suffer malnutrition (cachexia). At the same time the oxyhemoglobin does not break up, liberating its oxygen, therefore oxidation processes within the cell are greatly diminished, resulting in the accumulation of lactic acid. Likewise many of the blood and urinary changes, to which we shall shortly give consideration, may be due, at least in part, to such an alteration.

In epitheliomata, however, where the superficial structures are generally involved and therefore the action of the positive charge is intensified, we observe proliferation as in other neoplastic conditions and also at an early stage large particles of nucleus are often seen distributed throughout the cytoplasm together with marked hypertrophy of the cells.

This condition I believe to be brought about by the positive charge being so intensified as to cause complete degeneration of the nucleus of the cells, rather than cell division. Therefore, in epithelioma we have first degeneration of the nucleus if exerting force (positive charge) is direct and intensified, which, when degeneration is well advanced but not complete, a certain number of the surrounding normal cells are stimulated to proliferation. When this latter condition develops, and not before, does the real malignant character of the epithelioma manifest itself. With the formation of new cells we have the same proliferation and spreading degenerative conditions as suggested under the discussion on carcinoma.

Malignant tumors are differentiated from benign by the fact that the former possesses the power and property to form metastases which property is not demonstrated by the latter.

It must be remembered that it is not the histological property of the cancer cell that makes possible the classification given above. As stated before, there is no histologically typical cancer call, and this, together with the fact that metastases occur by the proliferation of the cells composing the tumor and not by a spread of cancerous degeneration, forces the suggestion that the property to form metastases must be due to an action similar to the one giving rise to the primary growth. This being the case it is reasonable to believe that at the offset there is no difference between an innocent and a malignant neoplasm, the property of malignancy being gained only through a long continued exposure to the new habit chemistry outlined earlier in this paper. Under these conditions the success of early extirpation or radiation can readily be accounted for.

As stated briefly in a preceding paragraph, the cell nucleus is composed primarily of a network (chromatin). Although this differs in different cells it is composed in all cases of two distinct parts, one an acid part (nucleic acid), the other a basic part (one of the simple proteins). Nucleic acid is composed of three groups, i. e., purine bases, pyrimidine bases and a carbohydrate group. Of these, the former I believe to be the most important, and should therefore be given first consideration.

Before considering these components of the cell nucleus, let us formulate a few facts already considered in order that the chemistry involved may be clearly understood. These conditions, which occur in the order mentioned, are as follows:

1. Checked oxidation causes accumulation of lactic acid.

2. Accumulation of acid causes accumulation of water.

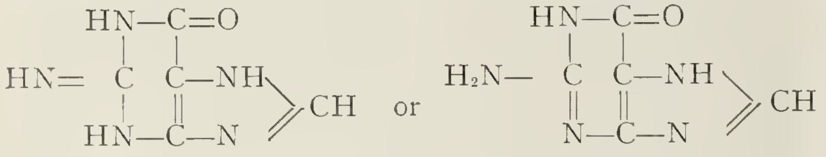
3. Colloids of cytoplasm take up more water in the presence of acids, with subsequent distention and pseudohypertrophy of the cell.

4. Swelling checks oxidation and blood supply.

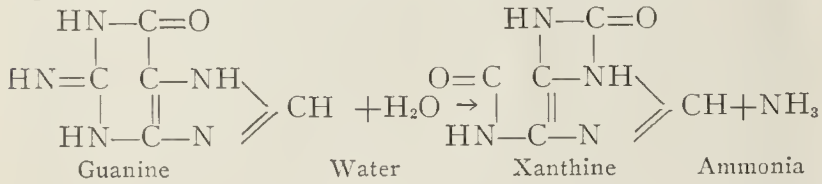
Thus we have a progressive pathological status established, to which the cancer cells adapt themselves. This new metabolism and habit chemistry established, we note the development of characteristic histological and chemical conditions known to accompany carcinomata.

Returning to the chemistry of our problem, Steudel and Levene found that nucleic acid contained two purine bases, adenine and guanine; study of the latter offers very interesting considerations.

Guanine, whose empirical formula is $C_5H_5N_5O$, or 2—imino —6 oxypurine, or 2—amino —6 oxypurine, has a structural formula of either:



Returning to the changes produced by an increase of water within the cell let us attempt to demonstrate a possible chemical change produced therein:



It can be seen from this reaction that the HN of the guanine is replaced by O with the formation of xanthine and the liberation of ammonia (NH_3).

With the increase of water there is swelling of the cell which checks further oxidation, therefore it is reasonable to believe that the oxidation of guanine which normally continues into the formation of urea ($Co(NH_2)_2$) is checked at this point resulting in an excess of xanthine and ammonia in the urine.

In cases of carcinoma of the stomach as well as of other organs, where there is an acid secretion (hydrochloric acid) some of the ammonia enters into combination with the acid secretion and thereby neutralizes some (hypochlorhydria) or all of the free hydrochloric acid of the gastric juice (achlorhydria) with the formation of ammonia chloride (NH_4Cl) which may remain as such or undergo further decomposition.

If oxidation is checked at this point, whereas normally it continues to the formation of urea, we could quite readily account for the decrease of urea demonstrated by many workers. As the proteins comprising the cells contain varying amounts of sulphur, we could, under these conditions, expect an increase in unoxidized sulphur in the blood and urine. This last condition has been demonstrated by Greene.

Up to this point I have endeavored to account for the following conditions observed accompanying malignant neoplasms of epithelial origin: proliferation and infiltration, hypoacidity, increase in lactic acid, increase in xanthine, urinary ammonia, decrease in urea and an increase in unoxidized sulphur. All of the conditions mentioned above have been reported by various workers and form the means of diagnosis in many questionable cases.

There still remain several important subjects for discussion that must await further research. However, experimental and clinical work directed along the lines suggested in this report offers encouraging results and shall form the text of future publications.

CONCLUSIONS.

1. In this hypothesis we have considered enzymes as catalytic agents, exerting their influence by the action of their electric charges and ionization. Antienzymes, on the contrary, we consider to bring about their action by the possession of opposite electrical charges from that possessed by their respective enzyme.

2. Although it is recognized that there does not exist a histological typical cancer cell in this hypothesis we endeavor to show that there does exist an electrochemical typical cancer cell.

3. That with the progressive pathological processes demonstrated in advancing stages of carcinoma there is established a new habit chemistry, under which influence the cell propagates and displays recognized symptoms accompanying the disease, and are formulated as follows:

a. Due to the influence of external cathonic stimuli (positive ray from the röntgen tube, alpha particle of radium, trophic nerves, etc.) the nucleic acid, normally anionic and composing a great portion of the chromatin of the cell nucleus, becomes, upon prolonged exposure, cathonic in reaction.

b. Due to the oxyhemoglobin of the blood being cathonic in reaction ionization and dissociation between these two compounds (cell nucleus and oxyhemoglobin) are inhibited, resulting in decreased oxidation and malnutrition (cachexia) of the cell.

c. Decreased oxidation results in accumulation of lactic acid.

d. With increased acidity the colloids of the cytoplasm take up more water, resulting in distention or pseudohypertrophy of the cell.

e. With increase of water there results a decreased oxidation and checked blood supply.

4. With the formation of the newly established habit chemistry above formulated, we are able to account for the following conditions accompanying the formation and development of carcinomata:

a. Proliferation and infiltration.

b. Excess of lactic acid in gastric contents.

c. Hypochlorhydria and achlorhydria.

d. Increase of unoxidized sulphur in the blood and urine.

e. Increase of xanthine in the urine.

f. Increase of urinary ammonia.

g. Decrease of urea in the urine.

5. If the hypothesis herewith presented bears any relation to the cancer problem, the possibilities of well regulated and early x ray and radium therapy suggest very promising results for the treatment, if not total cure of the disease.

6. I would suggest the possibilities of a treatment of cancer by the administration of protected anionic colloids (negatively charged, passing to the positive pole) due to their rapid and complete ionization, slow elimination, and particularly to their characteristic property of penetrating through the membranous covering of the cell and exerting their direct action upon the cell content. Colloidal sulphur is suggested, since large amounts of this substance can be given, due to its low toxicity and to the fact that large amounts introduced into and around the tumor, should exert a stronger ionizing effect; although the remaining anionic colloids, i. e., arsenic, iodine, silver, lead, mercury, antimony, etc., may be used. When the tumor is so situated that local treatment is impractical, such colloids may be administered per orem. Best results are, however, anticipated in connection with x ray or radium treatment.

7. The beneficial results reported of cuprase (colloidal copper hydroxide) and of colloidal lead, antimony and mercury, recently reported by Blair Bell, of Liverpool University, appear to be clinical application of the suggestion outlined in this report as such preparations are anionic colloids of their respective elements.

It must be remembered that this paper is purely a hypothesis and that I have now under way the tremendous amount of research necessary for its proof or disproof.

Medical Education and Some Medical Views Abroad

By JOSEPH S. DIAMOND, M.D.,
New York.

I approach the magnitude of this subject with much diffidence. Considering the vastness of the work which is going on continuously in physiology, chemistry, pathology, and in all branches of medicine, one can give but a cursory survey of a few phases of clinical medicine which are of interest to us, and refer in a general way to the spirit with which medical thought progresses abroad.

Aside from the well organized system of advanced medical teaching one is at once impressed with the character of the medical work in Central Europe. It may be divided into two types: 1, metaphysics of medicine, and, 2, mechanics and physics of medicine. I use the term metaphysics in order to describe the speculative thought, particularly of the inductive type as applied to medicine, dealing with inquiries as to the cause of phenomena and their conception. It is the philosophy which stimulates the interest and imagination and supplies the spark for deeper insight. As in all processes of evolution we see the practical developments taking root and with progress there ripens the finer and subtler type of thought so necessary for the understanding of the mysteries about us. In medicine, too, the law of immunology, the law of heredity, Fisher's conception of the synthesis of proteins, Hamburger's work on osmosis and ions, are all types of inductive thought.

RETICULOENDOTHELIAL SYSTEM.

An important chapter in medicine, of which one hears so much abroad and scarcely anything in our own country, is the reticuloendothelial system or apparatus, a term which was coined by Aschoff and originally called the reticuloendothelial metabolic system. It deals with the intermediary metabolism of hemoglobin, particularly with the production of bilirubin. An increase in its activity causes increased blood destruction. Upon the proper understanding of its function and the aberrations of its function depends the elucidation of the pathogenesis of the hemic diseases, such as pernicious anemia, hemolytic icterus, Banti's disease, and the aplastic anemias, and other conditions such as thrombopenia and scorbutus. The structure of the system consists of endothelial cells forming the capillaries of the portal circulation in the liver known there as the Kupffer cells. They also form the lining of the venous sinuses in the spleen and are also found in the hemolymph glands, in the bone marrow, in the alveoli of the lungs, and in the subcutaneous tissue of the body, known there as the plasma cell and histocytes. The affinity for iron and other colloidal substances of these cells has long been recognized by the followers of Ehrlich and was taken up by Aschoff and later by Eppinger. Eppinger has on numerous occasions injected solutions of organic iron into animals as well as into men just before death and was able to demonstrate, at autopsy, the deposition of the iron in these cells in large abundance. This can be easily demonstrated by the formation of Prussian blue by the reaction of potassium ferricyanide. The interest centred about the function of the recticuloendothelial system has aroused considerable discussion as to whether bilirubin is formed only in the liver or whether the other specialized cells in the spleen, bone marrow, subcutaneous tissue, lymph glands, etc., participate in the production, the liver acting merely as the excretory channel for this pigment.

HEPATOLIENAL DISEASES.

On the basis of the interrelation of the recticuloendothelial system, particularly between the liver and spleen and bone marrow and the hemolymph glands and their dysfunction, Eppinger has created the term hepatolienal diseases, including all the above mentioned diseases plus the degenerative toxic and inflammatory diseases of the liver and spleen such as are met with in the various forms of cirrhosis.

ICTERUS.

The old teaching of Naunyn that the production of all forms of jaundice are dependent solely upon the dysfunction of the liver and that with the extirpation of the liver, as he has done in the Avian species, no jaundice can be produced, this teaching tends to be overthrown in the light of the work done by McNee in Aschoff's laboratory, by the work of Whipple and Hooper, and recently by F. C. Mann of the Mayo clinic. Evidences tend to accumulate more and more that bilirubin is formed outside the liver, as the Eck fistula of Whipple and Hooper and the total extirpation of the liver of dogs by Mann have caused the appearance of jaundice and bile in the urine.

TESTS.

In the latter years numerous tests have been devised for the quantitative estimation of bilirubin in the blood as well as the quantitative estimation of urobilinogen in the feces. The significance of these tests is of great importance in estimating the rate with which blood destruction is going on and also the degree of impaired liver function. When we realize that neither the estimation of the number of red cells to the c.mm. nor the morphological appearances of the erythrocytes can tell us the rate of hematopoiesis or hemolysis which are constantly going on, or as Eppinger calls it the "tempo of blood destruction and blood production," then we see how important it is to study quantitatively the products of metabolism of hemoglobin as only in this way can we ascertain the exact amount of blood destroyed, and thus indirectly know the amount of blood produced? Hijman Vandebergh, of Holland, devised the quantitative colorimetric test for the estimation of bilirubin in the blood. It is a simple test requiring but a half c. c. of serum and will detect minute quantities as far as one to one half million. Normally there are found quantities of bilirubin in the circulating blood from 1 in 400,000 to 1 in 200,000. This test is of particular value in detecting early states of jaundice before the appearance of bile in the urine. Vandebergh found that the threshold of the kidney for bilirubin was 1 in 50,000, that is, there can be an accumulation of bile in the blood four to five times the normal before the pigment will appear in hte urine. Aside from the hemic diseases a slight increase of bilirubin in the blood is found in cholangitis, during and soon after an attack of cholelithiasis, so that it can be employed to advantage in the differential diagnosis between biliary colic and other forms of abdominal colic.

METABOLISM.

The world war has supplied considerable information as to the necessary requirements for the maintenance of a normal man in a nitrogenous equilibrium and the caloric needs per diem. The old standards of Voit and Rubner of 3,500 calories for a man weighing 70 kilograms were completely overthrown. During the war the food rations became gradually reduced to 800 calories as a minimum up to 1,500 calories as the maximum for a hard working man, that is, between 20 and 25 calories to the kilogram of body weight. The following changes, however, were noticed. A man weighing 70 kilograms in 1914 became reduced in weight to 55 kilograms in 1918, that is, there took place a gradual reduction of 2.25 per cent. of total body weight each year. These were the uniform findings both in Germany and Austria. Curious enough at this stage the body adjusted itself to this low intake so that there was no further loss of body weight, neither was there any interference in the performance of daily tasks. It is believed that the endocrines were responsible for this adjustment, causing the metabolic rates to take place at a lower level.

DIABETES.

Valuable information was also obtained as to the influence of this low food ration on diabetes mellitus. Statistics have shown that diabetes practically disappeared during the war. The patients became sugar free, their carbohydrate tolerance became markedly increased, they gained in strength and weight, and were able to resume active work. These effects, noted both in Germany and in Austria, were due chiefly to the diminution of the protein food, meats becoming scarcer and scarcer early in the war.

Falta has called attention to the fact that each hundred grams of protein metabolized yields in the process of combustion eighty per cent. carbohydrates; that for each gram of nitrogen metabolized five grams of carbohydrates are likewise metabolized from the same protein molecule. Therefore, in the establishment of a sugar tolerance one must never lose sight of the large amount of sugar derived from the proteins. One must also consider the type of protein, whether animal or vegetable, the animal protein being more dangerous than the vegetable, in view of its rapid assimilation and metabolism, the vegetable protein requiring a much longer time for its utilization thus providing an opportunity for the combustion of the carbohydrates.

The treatment of diabetes in vogue at the present time is the *Mehlfruchtenkur* or the cereal soup cure (based upon the original oatmeal cure of Noorden) or a combination of cereal and vegetable soups. Contrary to Allen and Joslin they maintain their patients on a higher caloric food value. They starve their patients very seldom, resorting to the fast days under rare conditions of acidosis. Their conception of acidosis differs somewhat from ours, inasmuch as they attribute the disturbed fat metabolism and the production of the ketone bodies, not only to the inability of the carbohydrates to be metabolized, but particularly to the presence of the proteins. Falta, who has perhaps done most of his work abroad, speaks of the protein as *l'agent provocateur,* the provocative agent that is responsible for the production of the ketosis. I have myself seen in the Falta clinic at Elizabeth Hospital a number of patients with acidosis where the fats were not withdrawn neither during the acidosis nor during the starvation period. The proteins were rigidly withdrawn while the patient continued on 150-200 gm. of fat a day in addition to Falta's cereal soups. I have seen no ill results. On the contrary the patients continued to improve, the acidosis disappearing and in time the sugar tolerance increasing with a gain in weight and in some cases restoration to health.

ENDOCRINOLOGY.

While the Germans are given to speculative thought, as a rule, it is surprising to see with how much caution and common sense they approach this subject. It seems that some of us in this country have allowed ourselves to run into fantastic speculation, attributing to endocrine dysfunctions almost every ailment to which human flesh is heir.

Working under tremendous difficulties on account of the high cost of apparatus for metabolic determinations, etc., their work can be compared quite favorably with the scientific investigations of Plummer and Boothby and also DuBois, Cushing and their coworkers.

Recently Zondeck, a young man connected with the Charité, has done some remarkable experimentation revealing the biological action of the endocrine to be dependent upon the balance of the ionic components chiefly of calcium, potassium, sodium and magnesium. He could produce either inhibition or stimulation of a strip of cardiac muscle, which effects were similar to a vagotonic or sympaticotonic reaction, when the cardiac muscle was kept oxygenated and transfused with the different ions of sodium, potassium, calcium or magnesium, the sodium and potassium having an inhibitory action, similar to a vagus effect, whereas the calcium and magnesium produced a stimulating effect similar to adrenalin and thyroid. He deduces from this that nerve reactions are dependent upon the equilibrium between these various ionic concentrations. Remarkable results can be attained clinically in all vagotonics by the intravenous injection of calcium chloride.

As to the treatment of Basedow's disease they also recognize the medical, röntgen ray, and surgical modes of treatment. X ray therapy in this disease has fallen somewhat in disrepute and is considered only mildly palliative. As to the etiology of Basedow's disease they regard it, not as a thyroid toxicosis, but as a dysthyroidism where there is the production of an abnormal secretion and not an increase of normal thyroid secretion. This hypothesis is utilized in the treatment of the disease by the use of homeopathic doses of iodides in the attempt to stimulate the remaining normal thyroid cells to counteract the dysfunction and produce a normal secretion. I myself have seen beneficial effects from this form of therapy, where the patients gain in weight steadily.

Interesting observations have been made as to the cardiac measurements in myxedematous states. The heart appears enormously enlarged in all its diameters, contracting very flabbily, at the same time the electrocardiograph showing an absence of the P. and T. waves and the venous pulse on the absence of the C wave. These conditions promptly disappear under thyroid medication, the heart often decreasing to one half its previous size.

The Steinach operation is very popular in Vienna but is regarded with disfavor in Berlin, and in many other things the Viennese and the German schools differ. For instance, during the many months that I spent in Berlin I never heard Freud's name mentioned either in or out of the university. As to the Steinach operation, it appears that for the first six months to one year miraculous results of rejuvenation can be brought about. Old men experience the stage of adolescence of a boy of eighteen. This experience, however, appears to be shortlived and is followed later by a period of depression which is far worse than the previous state. This is the German view. The operation has not been accepted in Germany and it is not advocated.

KIDNEY.

As to the status of kidney pathology, the clinical subdivisions or groupings seem to hold sway over the pathological classifications. In certain quarters, particularly by the pathologists of the Charité, there is an attempt made to smooth out the differences and to correlate the clinical and pathological findings. Roughly the present clinical subdivisions are recognized.

1. The degenerative types or the nephroses, such as are encountered in syphilis, tuberculous toxemia, febrile states, toxic states, diphtheria, pneumonia, influenza, mercury poisoning, etc. Here one finds the presence of lipoids in the urine which may be due either to a disturbed lipoid metabolism or to a lipoid degeneration of the renal epithelium.

2. The acute nephritis, more correctly designated as a glomerulitis, characterized by a primary inflammatory lesion in the glomerulus with secondary changes in the renal tubules, in view of the anatomical circulatory relation between the vas deferens of the glomerulus, to the tubule. These nephritides are found in many of the acute infectious diseases and in septic processes arising often from other infected foci. The war has shown that even pediculosis with infected scratch marks often results in the most severe glomerulitis. The involvement of the glomerulus may be diffuse, or it may be focal or embolic, or it may be unilateral and can then be mistaken for a surgical kidney due to unilateral hematuria.

3. Chronic nephritis or the secondary contracted kidney—a sequel of the acute glomerulitis.

4. The arteriosclerotic kidney which is divided into two classes: a, benign, and, b, malignant.

In the first only the larger renal vessels are involved and in the second the arteriosclerosis process extends into these smaller vessels and is called the arteriolosclerotic kidney.

5. Suppurative types: a, ascending; b, descending or hematogenous.

KIDNEY FUNCTION TESTS.

As regards the interpretation of kidney function, Europeans, the English school as well as the German, differ from us in the use of phenolsulphonephthalein. They do not advocate the employment of a foreign substance to test out the work of the kidney, but recommend the employment of substances which the kidney is called upon to excrete in the performance of its daily physiological activity. These substances are particularly water, salt and urea. The English recommend urea especially. Phenolsulphonephthalein is not employed at all. The English attempted its use for a while but discarded it in view of the lack of uniformity of results with their preparation. For surgical examinations indigocarmine is used.

The utilization of water as a kidney function test was originated by Schlayer and later modified by Volhard. In this country it was first used by Mosenthal and modified. It is known today as the Mosenthal test. The method as employed abroad consists of the administration of 1,500 c. c. of plain or aerated water on a fasting stomach and the urine collected every half hour for four hours. Normally it is found that eighty-five per cent. of the fluid is eliminated between two to four hours, the specific gravity sinking quickly to 1.000 and towards the end of the test returning to the normal. This is the socalled dilution test. The concentration test is carried out the following day and consists of the administration of solid foods only, withdrawing all liquids, and the specific gravity of the urine taken at each voiding. In the normal kidney the amounts are small and the specific gravity rises to 1.030 and over. The abnormal kidney can neither dilute nor concentrate, the volume, the specific gravity and the rate of elimination remaining unaltered under all conditions with but slight variations, depending upon the severity of the involvement. The socalled hyposthenuria and fixation become apparent.

Falta has conceived a subtler test for kidney function in the use of the potassium salts, administering 1,500 c. c. of normal potassium chloride solution. The test depends upon the principle of dehydration of the potassium ion. He found that when he gave to a normal man on a fasting stomach 1,500 c. c. of a normal sodium chloride solution, the water would be retained up to almost fifty per cent., contrary to the administration of plain water, where eighty-five per cent. would be eliminated within two to four hours. When, however, he substituted the potassium for the sodium salts he found that a normal man would eliminate 1,700 c. c. of water, that is, several hundred c. c. more than the intake. The effect of the potassium ion is to cause an osmosis of the fluids from the subcutaneous tissues into the blood, thus producing a hydremia, which is followed in the normal kidney by diuresis. If the kidney function is deficient, however, the amount of fluids excreted will remain constant and retain its low level irrespective of the hydremic state. It is thus seen that the contrast will be greater and the test more delicate.

EDEMA.

Important studies on edema were made by Eppinger. His observations on myomalacia cordis led him to a series of important scientific investigations. He found, in postmortem examinations, definite pathological changes in the thyroid gland similar to those present in myxedema. He noticed in all these cases that the patients had presented during life a low basal metabolism and continued to have a low consumption of oxygen even after the disappearance of the edema. He also noticed the beneficial effect of thyroid administration. These facts led him to conduct a series of experiments on dogs in which he studied the rates of absorption and elimination of water and sodium chloride in the normal dog and in thyroidectomized dogs. He made fistulas in the dogs' bladders and found that eighty per cent. of the water administered was eliminated in the normal dog within one hour, and in the thyroidectomized dog there was a marked delay. The same results in the delay of elimination were noticed with sodium chloride. He conducted these same experiments in patients suffering from myxedema and Basedow's disease and found similar variations in the elimination of water and salts. Furthermore, subcutaneous injections of sodium chloride solutions would remain indefinitely beneath the skin in the thyroidectomized dogs. He made similar observations on the absorption of saline from the skin by the aid of the plethysmograph in myxedematous and in Basedow patients. The results were always similar. He carried these observations further to patients suffering from nephroses and found a low basal metabolism and similar lack of absorption of water and salts as observed with the plethysmograph. It is then that he established the relation between nephroses and the thyroid gland, the extrarenal component in the nephroses.

His experiments on the mobilization of sodium chloride and water revealed that the skin was the natural or physiological storage house for salt and to a less extent for the water, and that if twenty grams of sodium chloride were administered it would first be deposited in the skin but not in the internal organs and that it would require at least twenty-four hours for its elimination. The potassium salts are not deposited in the skin but in the internal organs, in the skeletal muscles, the heart, the brain, etc. In the heart the potassium content is very high normally. In those patients dying of cardiac insufficiency in waterlogged states he found a diminution of potassium and a replacement with excessive deposits of sodium in the interstices of the heart muscle and edema. He advises strongly the administration of potassium salts in large doses in all these cases before any cardiac stimulants are administered.

In the edemas of nephroses and nephritides the lack of elimination of sodium chloride and water is not due to the lack of kidney elimination but to the changes in the peripheral capillaries which are analogous to the changes in the glomeruli and in the renal epithelium. The increased permeability in these capillaries for albumin is the cause, in Eppinger's opinion, of the production of the edema. Similar changes he finds in pulmonary edema, where the alveolar capillaries allow the passage of albumin and water into the lungs. Similarly one finds in edema of the brain in inflammatory states the presence of albumin in the cerebrospinal fluid. In his experiments with the dialyzable membrane, if one adds albumin to the solution of sodium chloride, the sodium chloride will promptly cease to pass out. On the other hand, if one adds trypsin and the albumin undergoes digestion, the sodium chloride will then again begin to dialyze. The thyroid extract causes an improvement in the metabolism of the albumin and therefore controls the edema. In his opinion diuretics act, not by causing an increased hydremia and not directly as stimulants of the renal epithelium.

RÖNTGEN RAY.

Fluoroscopy is used abroad to far greater advantage than in the United States. It has always been preferred to plates even before the war when the question of expense did not exist. It is remarkable to what finesse they have developed the art of fluoroscopy and with what diagnostic acumen they recognize any aberration from the normal. All their diagnoses are reached by the fluoroscope. It is seldom that plates are used. Occasionally they take a plate of the stomach, but it is more for exhibition in the clinic and for the record than it is for diagnosis. Most of their records are kept by sketches and tracings over the fluoroscopic screen which, by the way, is made use of in every single case. Cardiac measurements are ascertained, pleural effusions, tumors of the lung, aneurysms, tuberculous infiltrations, are all traced and observed from time to time, comparing the various tracings as to the progress of the disease. Tracings are attached to each patient's chart, another set of tracings remaining in the laboratory for record. The fluoroscopist of the institution does nothing but fluoroscopy and remains in the dark room from morning till night, using remarkably little protection. I have seldom seen gloves used, not to mention rubber aprons and lead glasses. As to their plate work, it is much inferior to ours. They seem to have stood still in the technic of röntgen plates and they are at least fifteen years behind. Films are unknown, glass plates being still used. Many of the plates are nondiagnostic and would not be used in our institutions, to say nothing of our private practice. Their technic is poor, almost all their lung plates blurring of respiration. As to the accuracy of diagnoses, Haudek has told me of a number of occasions where he diagnosed the presence of a gastric ulcer which the surgeon could not find upon opening the abdomen. Haudek, however, persisted as to its presence and indicated the exact location, and upon the strength of his word many times a pylorectomy and even a gastrectomy have been performed; the pathologist invariably finding the niche in the resected portion.

PATHOLOGY.

Virchow's cellular pathology still holds sway in Central Europe, although undercurrents of skepticism are apparent as to the explanation of all phenomena of aberration of function upon structural cellular changes. Lubarsch in his studies of a series of cases of achylia gastrica of a functional nature was unable to discern postmortem any alteration in the morphology or staining characteristics of the goblet or parietal cells of the stomach. Similarly Dresel working at the Charité on the autonomic nervous system was able to produce glycosuria in animals by *piqûre* of the corpus striatum at the nucleus pallidus. Under prolonged glycosuria the islands of Langerhans of the pancreas showed no structural changes.

We in this country and the English having their chief exponent in Mackenzie recognize more the importance of function and its lack of dependence from structural cellular changes. When we consider the rôle played by the body fluids, the hydrogen ion concentration, surface tension, and the extracellular immune bodies found in disease; and when we consider the secretions, enzymes and hormones and their far-reaching influences, the entire subject of physical chemistry with the innumerable interchanges and reactions continuously taking place, upon which life depends, we can then understand the importance of function both in health or disease. When we further consider the influence of constitution and the status and how these may modify function without any alteration of cellular structure, we then have a fair picture of the significance of function and its independence of cellular pathology.

FACILITIES FOR WORK.

As to the facilities for work abroad I wish to say that in Central Europe one finds a well organized system of medical instruction, most efficiently carried out in Vienna. Their organization consists of a body of splendid teachers, a group of men representing all branches of medicine who love to teach and who have made teaching their life work. Most of these men are gifted in the art of teaching and can give courses in three or four foreign languages, English, French, Spanish, and Italian. Most of them speak English fluently.

I need not dwell upon the abundance of the material and the rich clinics when we consider that the Allgemeine Krankenhaus in Vienna has six thousand beds from which to draw upon for study. I shall perhaps mention the type of the available material which is of great interest. Their public patients differ a great deal from our own, inasmuch as each individual patient feels that he must offer himself as an object for study. We treat our patients more humanely, with courtesy and consideration. Our patients expect this attention. Not so on the other side. Our patients would not submit so readily to the many tiresome examinations. I had occasion to witness a case where a patient was brought down to the eye clinic only a few days following a laparotomy for gastric ulcer, because he presented an interesting eye fundus.

PHYSICAL DIAGNOSIS.

Among other things it was refreshing to see with how much precision they applied themselves to physical diagnosis. It was astonishing to see how accurately they percussed cardiac borders and how well they corresponded with the fluoroscopic tracings. It is still a vital and important art, for unlike the stethoscope one does not carry a fluoroscope in his pocket.

As to pathological material one has the opportunity to study the material of ten autopsies a day. I need not mention the exactness and the detail with which these cases are presented. All the important data with their previous records are brought forth and the pathological findings are presented grossly and microscopically by the aid of projectoscopes, frozen sections being prepared the same day for the class.

With all this, however, I feel that America is destined to become in time the leading centre of medical education. From the perspective we can appreciate our own country better. In the mechanics and physics of medicine today we lead the world. Our surgical technic is surpassed by none. In the great field of physical chemistry such names as Gibbs, MacClandan, Loeb, VanSlyke, Folin, and Benedict stand out preeminently all over the world. In this prolific field of research, which bids fair to equal in importance that of the discovery of germs, we are no longer followers but leaders.

The two main obstacles that confront us at the present time are the lack of full time competent teachers and the lack of sufficient autopsy material for pathological work. In the first, our philanthropists should come to the rescue in establishing adequate funds for the encouragement of full time teachers, and as to the second, the laws should assist us in obtaining the necessary material.

In conclusion, one cannot fail to be impressed by the splendid group of men abroad. In Germany, Aschoff, Friederich Müller, Kraus, Hiss, Goldscheider, Brugsch, Bickel, Umber, Assman, Frankel, Minkofsky and a host of others. In Vienna, Chvosteck, Ortner, Wenkebach, Holzknecht, Haudek, Eppinger, Falta, Kovach, Erdheim, Hess, Freud, and Eiselsberg. One cannot but admire their sincere devotion and how stoically they stand the sacrifices under the stress of the times. When we consider that most of these are full time men with a fixed salary from the government equivalent in our money to eight or ten dollars a month, but a half to a third of the salaries of the working people, we can then realize their plight. To see a man like Eppinger, who to my mind is today the greatest medical thinker of Europe, to see this genius running from the ward to the research laboratory and then to the teaching class and from there to the autopsy room and then again into the fluoroscopy room, snatching a black bread sandwich in between, is both an exalted and a pitiful sight to see. Let us rise to their rescue. As H. G. Wells remarked in 1919 after his visit to Soviet Russia, "Scientists and artists have a mission to fulfill, each one in the performance of his specialized work. Unlike the laborer they cannot assume any type of work as the emergency of the times may call for. Deprive them of their work and they die." Therein lies the explanation of the unceasing and unselfish devotion to their work. They have their mission to perform. Deprive them of it and they perish.

110 East Sixty-fourth Street.

A Gravity Method of Blood Transfusion*

By TRACY L. FISK, M.D.,
New York.

All is not well at the present moment with the art of blood transfusion. Carrel states flatly (1) that the piston methods of transfusion are wrong in principle, and must, in the long run, prove dangerous in practice. Almost simultaneously Bernheim (2) and more recently Unger (3) have published papers showing that there is an increased morbidity and an increased mortality when the citrate method is used, as compared with the methods which transfuse uncitrated blood. Thus from high authority come criticisms of the two methods which in this city are used almost exclusively,—criticisms so severe that it is scarcely likely that either of these now popular procedures can remain much longer the method of election in the best hospitals, however long they may survive in military and rural practice, and in cases where special indications must be met. This statement will certainly not pass unchallenged by the exponents of the present methods. I expect but little support from the leading workers in this field, because each is the father of his own particular method, and is bound by the rules of parenthood to support his own child.

Before discussing the good and bad qualities of the different methods of transfusion, let us briefly consider some important characteristics of blood. This fluid tissue, for it is no less, consists of myriads of living corpuscles, themselves exceedingly fragile and prone to disintegrate upon slight trauma, which float in a plasma that tends to undergo remarkable physicochemical changes with great rapidity. Thus for physical delicacy and chemical instability the blood is without any parallel in nature.

For the present, we may consider only the phenomena that constitute or accompany coagulation. Blood remains fluid as long as it is contained in living and healthy vessels, and as long as it does not touch any foreign body or clot inducing substance. However, when the blood is shed, changes are usually instituted which lead to the formation of a coagulum within three to ten minutes. For our purpose it is not necessary to review the vast literature of clot formation, nor to learn the complex theories of the interaction of cellular elements, thrombokinase, calcium salts, thrombogen, thrombin, fibrinogen, and the endproduct, fibrin. Suffice it to say that when the blood touches any substance that it is capable of wetting, e. g., steel, glass, paper, or rubber, it clots rapidly. This does not happen for a long time if the blood, when shed, is received in a vessel lined with a substance that cannot be moistened by the blood,—a blood repelling substance like paraffin or petrolatum. Apparently any substance that is wet by the blood exerts a traumatic or destructive action on the formed elements, notably the platelets, which at once give off clot forming or thromboplastic substances. Even then, if calcium salts are not present in the plasma in available form, no coagulation can occur. These characteristics are important to the worker in transfusion for several reasons. Massive coagulation at any stage of transfusion mechanically stops the operation. Also, the introduction of clots, even if small enough to pass through the needle, into the recipient's vein, constitutes a grave danger. Furthermore, there is evidence that the reactions that follow transfusions are in many cases due to changes in the blood antecedent to clotting.

Let us take up the advantages and drawbacks of the various methods of transfusion.

1. Direct transfusion by arteriovenous anastomosis. This is one of the oldest methods. The radial artery of the donor is exposed for two inches, and a vein of the recipient is exposed for an inch. The artery is divided, and the vein is incised. The proximal end of the artery, from which the blood is spurting, is inserted into the vein about an inch. In order to estimate the quantity of blood transfused, the operator, before inserting the artery into the vein, may receive a certain number of spurts of blood in a measuring glass. Experience has shown, however, that this mode of measuring the blood is grossly inaccurate. This ancient method transfers a pure, unaltered blood. In this respect it stands first of all methods. However, it has fallen into disuse because it inflicts a painful dissection upon both donor and recipient, it destroys the donor's radial artery, and it provides no accurate measure of the quantity of blood transfused.

---

*Read before the Bronx Medical Association, February 1, 1922.

2. The paraffined bottle of Kimpton and Brown. This method consists in the reception of the blood in a paraffin lined bottle or flask. Venous blood is used,—a great advance over the older methods which destroyed an artery. The Kimpton-Brown method is good in that the blood touches only paraffined surfaces, and may be transported a short distance if necessary. The disadvantages are that the method is not always successful, since clotting sometimes takes place before the completion of the transfusion, and that the blood, in any case, is about fifteen minutes outside the human vessels. No man knows what changes may take place in that magic fluid in fifteen minutes. In the method that I use, the blood is out of the human vessels only about one second, while traversing a seven inch tube.

3. The piston methods. The late Edward Lindeman described a "simple syringe transfusion with special cannulas." His plan was indeed simple in conception, as he merely withdrew blood with a piston syringe from a vein of the donor, and injected it into a vein of the recipient. However, in order to transfuse a sufficient volume of blood, six hundred c.c. or more, the operator was obliged to fill and empty his syringe many times. Lindeman insisted that the syringe must be washed after being used, before being refilled. An assistant was required for this part of the work. It was necessary also for one operator to withdraw blood from the donor's vein while another injected blood into the recipient's vein. Thus the transfusion required three skilled workers who could operate in perfect synchronism. Unger, Bernheim, and many others sought to simplify Lindeman's method. They did indeed save labor by omitting or reducing the frequency of rinsing of the syringe, and by substituting a rotary valve or plug for the troublesome method of connecting and disconnecting the cannulas. Lindeman's method and its modifications have the advantage that they keep the blood out of the veins only about seven to ten seconds.

The disadvantages of Lindeman's method are: It is laborious and calls for perfect teamwork; much blood is lost at the donor's cannula; contamination of donor's cannula with recipient's blood may occur; the cannulas are not paraffin coated, though they are coated with albolene (it is doubtful that albolene remains in the cannula when washed with warm blood); the blood is subjected to at least four forms of trauma, i.e. it is churned by manual power through the inordinately small nozzle of the Record syringe, while in the glass cylinder it is subjected to violent changes of pressure, some of the formed elements are triturated between the piston and the wall of the cylinder, and mere contact with the bare glass of the cylinder causes trauma of the platelets, with setting free of thromboplastic substances. Lindeman was aware that the blood suffered trauma in the syringe, and to minimize this danger, he insisted on incessant washing with sterile water. But Bernheim, in describing his modification of the method, speaks of refilling a syringe two or three times before washing, and Unger goes a step farther and uses a syringe repeatedly until the transfusion is completed. Each of these instruments is a veritable mortar and pestle. It will be urged that only a few cells are caught between piston and cylinder. This is doubtless true, yet a few are sufficient to give up enough thromboplastic substance to incite clotting.

4. The sodium citrate method. This method, matchless in its ease and simplicity, merely requires the addition of 0.25 per cent. sodium citrate to the blood as it is received in a flask or other vessel. Once citrated, the blood will remain fluid for two days or more so that even the novice will have time to inject it into the recipient. The method, introduced independently in 1915 by Lewisohn of New York and Agote of Buenos Ayres, at once attained great popularity. Almost immediately, however, it was noticed that chills and high temperature followed citrate transfusions far oftener than pure blood transfusions. At first it was thought that these reactions were devoid of real danger. However, after about six years' experience with the method, operators began to report fatalities, some of which occurred long ago. The method is still widely used, but evidence is accumulating that it is not so safe as the methods which transfuse uncitrated blood. The paper read by Bernheim (2) at Boston last June, and the important discussion which followed, showed that the profession is now aware of the risks of the citrate method. Yet, as Lewisohn said at that time, our object should be, not to abolish the use of the citrate method, but to divest it of its dangerous feaures. The socalled citrate reaction occurs in about twenty per cent. of the cases in which blood is transfused by the citrate method. A similar reaction occurs in about five per cent. of the recipients of uncitrated blood. It is possible that the same cause is present in both instances. Possibly trauma of the formed elements, which undoubtedly occurs in marked degree with the citrate method, is the cause of the reactions. This trauma may be in part avoided by the use of paraffin lined vessels, tubing, and needles, in connection with the citrate method.

5. The gravity method of transfusion. Last summer I asked Dr. Carrel what method of transfusion he considered the best. He replied that of the methods used today, none was satisfactory in principle. That a procedure should be perfected by which the blood could be transfused from the vein of the donor to that of the recipient through a tube which would not allow coagulation; at the same time, a device should be made to measure the amount of blood transfused. (During the war, Dr. Carrel performed transfusions with a simple vein to vein paraffined silver tube. However he had no exact measure of the amount of blood transfused.) Subsequently to this conversation, a friend (Dr. Clarence Smith) suggested that the donor be weighed before and after the transfusion. Upon this hint I based the gravity method. However, the donor is not weighed before and after,—on the contrary, the donor, or better, the recipient, is on the scale during the transfusion.

Apparatus used. A platform scale, capacity three hundred pounds, sensitive to variations of one quarter ounce. The scale I use is a Fairbanks silk scale. No clinical scale and no automatic scale of this capacity would be sensitive to one fourth of an ounce. The scale mentioned is a result of the demand of the silk trade for a weighing instrument of large capacity and extreme accuracy. It is portable. I had the beam cut by the makers with metric graduations. Otherwise it is a stock scale. Its accuracy is remarkable.

Two wooden tables, eighteen inches wide, eighty inches long. The donor's table is thirty-two inches high, the recipient's table is of such height that when it is in position on the scale platform, it will be six inches lower than the donor's table. This difference in level augments the flow of blood from donor to recipient. The tables fold and are portable.

Two arm rests. In each case this is a thin oak board about three and one half inches wide. The recipient's arm rest is straight, as it is used in a horizontal position. The donor's arm rest bends sharply downward from the edge of the donor's table, at an angle of forty-five degrees.

The tourniquets should be red rubber tubing, one quarter inch diameter, eighteen inches long.

The blood carrying tube is pure gum five-thirty-seconds of an inch inside diameter, seven-thirty-seconds of an inch outside, seven inches long. At each end is an adapter for attachment to a Fordyce needle. Most adapters have a small lumen, and should be drilled to a diameter of one eighth inch.

The needles are Fordyce needles No. 12, 13, and 14 (English wire gauge). The 13 gauge is generally the best. For children a 16 gauge needle is suitable. A hot mixture of paraffin and petrolatum, fifty per cent. each, is drawn through each blood tube and each needle, after which they are sterilized by steam in a vertical position, examined for patency, and resterilized.

TECHNIC.

Both arms of both patients are inspected, as either arm of either patient may be used. The recipient lies on his table on the scale platform. His chosen arm is placed upon his arm rest, which extends horizontally toward the donor's table, all contact being avoided by the difference in level of the tables. If the umbilicus of the recipient is over the center of the scale platform, he will be sufficiently well balanced for accurate weighing. The donor lies on his table, which is about eighteen inches from the recipient's table. The donor's arm is on his arm rest, which inclines sharply downward, so that the median basilic vein of the donor is close to that of the recipient. A space of half an inch is maintained between the arms of the two patients. The recipient is weighed, and if necessary, a small additional weight is placed on the scale platform, so that the beam will balance with the poise close to the zero mark on the beam. If the poise then happens to be at the 20 G mark, and it is desired to transfuse 600 G, the final resting-place of the poise will be at 620 G. This end point should be decided upon, but the poise need not be placed there at once. Tourniquets are applied to the arms of both patients, the donor's tourniquet, especially, being snugly placed. The fields are sterilized with iodine. The operator now introduces a 13 gauge Fordyce needle into the vein of the recipient, and at once the nurse releases the recipient's tourniquet and removes it. A spurt of blood, followed by a steady flow, should mark a successful entry of the recipient's vein. If the puncture of this vein is satisfactory, the operator at once introduces another 13 gauge Fordyce needle, attached to the rubber blood carrying tube, into the vein of the donor. While the blood is flowing in good volume from the tube, it is quickly attached to the recipient's needle. The transfusion now proceeds automatically. The nurse follows the rate of flow by shifting the poise on the scalebeam. If for any reason the flow should cease, the scalebeam would cease to rise. With good veins and a successful puncture, the flow is very constant, and the beam tends to rise steadily until the nurse has gradually pushed the poise out to the point which has been decided upon as the endpoint. When the poise is at this point, and the beam is balanced, the transfusion has been completed. The operator then compresses the rubber bloodtube to stop the flow. At the same time he releases the donor's tourniquet. While still compressing the tube, the operator withdraws both needles from the veins, and elevates the arms of both patients to prevent bleeding from the little needle wounds. Sterile compresses are applied, and the arms may be brought down after about three minutes.

Use of this method in hospital and private cases convinces me that, 1, in transfusions in which donor and recipient have welldeveloped veins, the method is astonishingly easy; 2, in cases where one or both of the patients have veins that will barely admit a 14 gauge needle, the method may be used by a skilled intravenous worker without any great trouble, but the novice will fail; 3, in difficult cases, where the veins are exceedingly small, or have been thrombosed or infiltrated by arsphenamin, the method, like all pure blood methods, can be employed only by an intravenous worker of rare skill. Even if such an operator be available, it is better, in my opinion, in the face of such formidable difficulties, to use the paraffin-citrate method already referred to, in which the blood is citrated, but is kept in a paraffin lined container, and is received and delivered through paraffin lined needles and tubes.

The gravity method calls for rather bulky apparatus. However, in an emergency, everything may be dispensed with, except the tube and two needles, paraffined and sterilized, and two tourniquets. In such a case, the amount of blood transfused would be judged by effect upon the recipient.

In the use of a simple vein to vein paraffined tube, I assert no priority, since other workers, notably Carrel, have used such a tube. They, however, had no means of measuring the flow, except the laborious and at times very inaccurate method of Libman and Ottenberg.

I would repeat that patients whose veins, on inspection, are found to be very small (smaller than a 14 gauge needle) are not eligible for the gravity method, because the gentleness of the propulsive force employed, precludes the use of fine needles.

Sixty to seventy-five per cent. of all cases are eligible for the gravity method, and ought, in my opinion, to receive the advantage it offers.

The author's references will appear in his reprints.

Miliary Carcinosis*

By ELMER H. FUNK, M.D.,
and B. L. CRAWFORD, M.D.,
Philadelphia, Pa.

Metastatic malignant disease of the type exemplified by the present case is so uncommon that we believe it worthy of recording.

CASE.—E. A., K-2306, female, white, aged twenty-eight years, was admitted to the department for diseases of the chest of the Jefferson Hospital, September 15, 1921, and died September 20, 1921. Her family history was negative. She had had measles and pertussis in childhood, influenza in 1918, and some mental disturbances in the summer of 1919, for which she was a patient in the Philadelphia General Hospital for four months. She recovered entirely from this trouble. An abdominal section was performed in February, 1920, for tuberculous peritonitis, and at operation an ovarian cyst was found and removed. Menses were normal. She had four children living and well.

Her present illness began on July 4, 1921. The patient was seized, after exposure to wet, with a sharp pain in the right side, aggravated by deep breathing and associated with a dry cough. The pain lasted for two weeks, during which time the cough became worse and slightly productive. Shortly afterward attacks of sweating occurred and were associated with progressive weakness. Early in the course of the illness shortness of breath developed. It was slight at first but increased in severity until she was compelled to go to bed on account of this symptom as much as for the distressing cough and weakness.

Condition on admission.—When admitted to the hospital she was quite weak, dyspneic, cyanotic, feverish, and distressed by a frequent hacking cough. At times this cough was productive of a considerable amount of yellowish sputum which on one occasion was bloodtinged. She had no pain. Emaciation was marked and her relatives told us that she had lost a great deal of weight since the onset of the illness. She had weighed 146 pounds in 1913 and this was about her average weight before the present illness. Her last weight, about two weeks before admission, was 111 pounds. She was so sick upon admission that it was not possible to weigh her. The physical examination revealed a pallid conjunctiva, pupils equal and reacting normally, ocular movements normal, ears normal, tongue coated with a whitish fur, lips cyanotic, throat red and injected. The neck showed no palpably enlarged glands. Examination of the chest revealed rapid and shallow respiration (36 to 40 a minute) with greater limitation of movements on the right side. The percussion note was hyperresonant throughout the pulmonary area. The breath sounds were generally somewhat suppressed, except over the apices, where they were quite harsh. The expiration was almost inaudible but when heard seemed prolonged. Auscultation of the breath sounds was quite difficult in places because of the enormous number of fine and coarse crackling râles everywhere. The heart action was rapid and the sounds weak. The abdomen was slightly distended but not rigid nor tender. No masses were palpable. An old scar of previous operation was visible and in midline below the umbilicus. The extremities showed distinct cyanosis of the finger nails, but no clubbing. The temperature ranged from 100° to 101.4° and the pulse averaged 120. Examination of the urine revealed an acid reaction, light cloud of albumin, numerous pus cells, and a few granular casts. No studies for tubercle bacilli in the urine were made. Four sputum examinations were negative for tubercle bacilli. The leucocyte count was 12,900. No differential count was made.

Diagnosis and progress.—The clinical history and physical findings suggested an acute tuberculosis, either of the localized type known as acute bronchopneumonic tuberculosis or the pulmonic form of acute miliary tuberculosis. We were uncertain, but rather inclined to the latter diagnosis. Shortly after admission the patient became rapidly worse, with profound prostration and delirium, and died on the fifth day. A necropsy was secured and instead of finding a miliary tuberculosis, the lesions present were those of a miliary carcinoma. The gross appearance of the lung was so like that of a miliary tuberculosis that at first glance it was considered tuberculous. A feature which caused some comment was the absence of any evidence of an old lesion of tuberculosis at the top of the lungs. Upon examining the other organs, however, especially the liver, the malignant character of these miliary nodules became quite apparent. In the liver they were somewhat larger, several approaching one half to one cm. in diameter, rather sharply defined against the surrounding liver tissue, firm on section, and free from any evidence of caseation. It was at this point that it occurred to us that the ovarian cyst removed February 6, 1920, that is, almost twenty months before, might have had malignant changes. Subsequently we were able to obtain the cyst specimen and sections revealed the changes of adenocarcinoma.

NECROPSY REPORT (ABSTRACT).

Pleural cavities.—The left pleural cavity contained considerable bloodtinged fluid. A number of dense adhesions were present between the layers at the apex and posteriorly. On the right there were numerous dense adhesions and several hundred cubic centimetres of reddish fluid.

Lungs.—The left lung weighed 850 gms. The organ contained consolidated areas throughout; the greater portion of the lower lobe and the lower third of upper lobe were practically airless. The remainder of the upper lobe contained numerous small nodules throughout; on section the lung tissue offered little resistance. The incised surface was red and dotted with numerous yellowish foci; on pressure a rather thick, yellowish, bloodstained material exuded. The bronchial mucosa was very red and covered by a thick sticky mucus. There was no evidence that the lung tissue was breaking down. The peribronchial nodes were only slightly enlarged and red. The right lung weighed 970 gms. and was heavy, nodular and firm. The pleural surface was red. The lower lobe and posterior portions of the upper lobe contained nodular and consolidated areas. The incised surface was red and dotted with innumerable small yellowish foci, and exuded a sticky yellowish fluid. The bronchial mucosa was uniformly red and covered with sticky mucus. The peribronchial nodes were slightly enlarged and red.

---

*Presented before the Association of American Physicians, Washington, D. C., May 3, 1922. From the Department of Medicine and Pathology, Jefferson Medical College, Philadelphia.

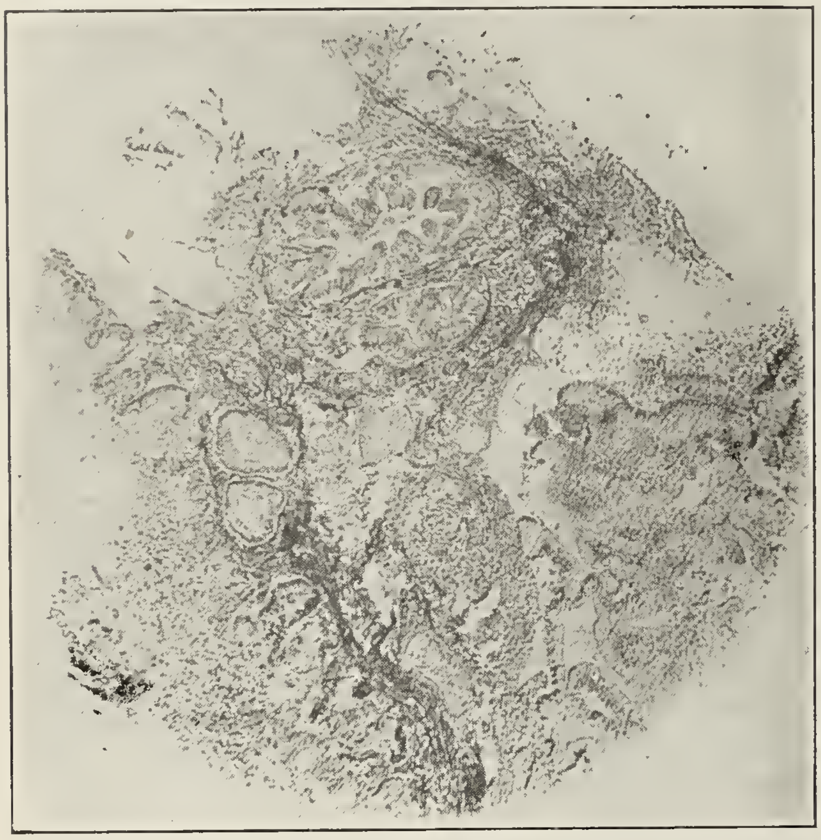


Fig. 1.—A section from ovary removed at operation showing the irregular acini lined by the tall columnar epithelium and also many small papillæ. This same type of growth was found in the other organs at necropsy.

Spleen.—The spleen weighed 150 gms., was soft in consistency and normal in shape. The incised surface was soft and deep red.

Kidneys.—The left kidney weighed 140 gms. and was normal in shape and consistency. Circumscribed yellowish foci were adherent to the capsule and extended into the parenchyma. The normal markings were distinct and the tissue was slightly congested. The right kidney weighed 140 gms., was red in color, and the markings were fairly distinct. No nodules were observed in this kidney.

Liver.—The liver weighed 1,370 gms. and was rather soft. The surface presented a number of small, sharply circumscribed, greyish nodules varying in diameter from two mm. to one cm. The incised surface of the organ appeared normal. The gallbladder and bile ducts were apparently normal.

The adrenals showed no macroscopic change. The stomach and intestines showed no gross lesions. A number of the mesenteric and perigastric lymph nodes were enlarged, firm and greyish in appearance on section. A number of lymph nodes along the vertebral column were enlarged, firm and grey. On the right side of the vertebral column, opposite the first lumbar vertebra, the thoracic duct was markedly dilated and contained a thick yellowish fluid.

The uterus and vagina were normal. The right tube and ovary were absent as the result of removal at previous operation. The left tube was enlarged, red and adherent to the pelvic tissue. The left ovary was enlarged and cystic. In the right side of the pelvis at the site of the previous operation was a firm, irregular nodular mass about the size of an English walnut, densely adherent to the inner surface of the ilium; and just above the brim of the pelvis were a number of enlarged postperitoneal lymph nodes. The aorta and other large bloodvessels appeared normal.

Gross diagnosis.—Acute bronchopneumonia. Diffuse consolidation of both lungs with numerous miliary foci scattered throughout. Chronic adhesive pleuritis with superimposed acute serous pleuritis. Acute salpingitis (left). Probable tumor metastases to liver, lung, postperitoneal and mesenteric lymph nodes, left kidney, and pelvic tissues.

Histological diagnosis.—(Figs. 1, 2, 3, and 4). Adenocarcinoma, metastatic, involving lungs, liver, left kidney, mesenteric and postperitoneal lymph nodes, thoracic duct, and pelvic tissue. Bronchopneumonia. Papillary adenocarcinoma (primary) of right ovary removed at operation twenty months before death of patient. Note: The origin of the tumor found at necropsy could not be definitely determined until the right ovary previously removed was sectioned and examined. This ovarian mass consisted of large cysts which had been opened. The walls were thick and contained small cysts filled with gelatinoid material.

COMMENT.

A retrospect allows of certain comments from the clinical and pathological viewpoints. In a recent clinical contribution (1) attention was directed to one group of cases with malignant disease of the lung in which the clinical features were not unlike those of acute miliary tuberculosis. A primary focus is common to both; and secondary miliary deposits occur from invasion of the blood stream by bacterial emboli in tuberculosis and neoplastic emboli in carcinosis. The knowledge of the existence and character of the primary focus suggests the diagnosis in many cases, in others the obscure character of the primary lesions makes the diagnosis almost impossible. The primary tumor may be in the bronchus, as in the case reported by Elisberg (2). West (3) refers to two reported cases in which patients with cancer of the face developed cough and expectoration with loss of strength and flesh; the necropsy revealing the lungs studded with minute nodules of new growth and dissemination in various organs of the body. Fagge's (4) patient, a man of fifty years, died of bronchitis with pneumonia. The necropsy revealed both lungs studded with nodules, the largest being the size of hemp seed. There were nodules in pericardium, left ventricle, liver, and spleen.

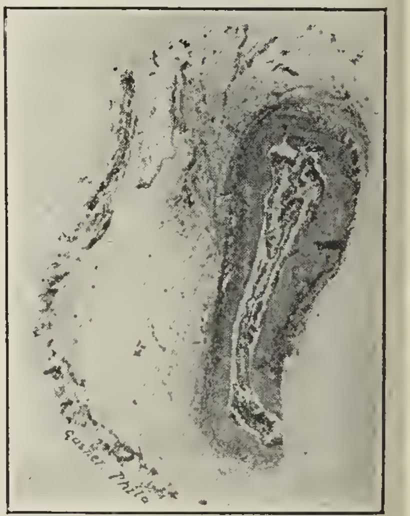

Fig. 2.—A section of the thoracic duct showing tumor cells practically obliterating its lumen.

In the absence of any obvious primary growth, miliary carcinosis is more likely to be mistaken for acute tuberculosis than acute tuberculosis for miliary carcinosis. The sputum examination offers little help when negative, since it usually is negative for tubercle bacilli in miliary tuberculosis unless there is an associated old open lesion at the apices. The presence of the tubercle bacillus in the sputum may not be conclusive evidence of the miliary nodules found postmortem, since both diseases have been found in the same lung. In 1878 S. W. Gross (5) reported before the Pathological Society of Philadelphia, a case in which at necropsy both metastatic deposits and tubercles were found. The patient, a woman, was known to have a scirrhous carcinoma of the breast for seventeen and a half years. During the last year of life she had suffered from cough, occasional slight hemoptysis, and other signs of tuberculosis. At necropsy both lungs showed tubercles, especially the right in which several small cavities were discovered. The lungs were also filled with metastatic scirrhous deposits which varied in size "from a small shot to a cherry." The history of a known malignant focus or a known tuberculous focus in the body ought to suggest the character of the acute illness in this group of patients. It might be argued that our bacteriological and histological knowledge has increased since Gross's time, and the tubercles which he found in addition to the "metastatic deposits" may have been metastatic lesions of a different character and that tuberculosis really did not exist. Gross's knowledge of pathology and the presence of small cavities lead one to believe, however, that he was right in his assumption of the presence of the two diseases. That the history may mislead in the diagnosis, is emphasized by the experience of Hadden (6), who reports the case of a man who following an operation for anal fistula presented symptoms suggesting acute tuberculosis. Death occurred within a fortnight and at autopsy the naked eye appearance of the organs was that of an acute tuberculosis, but the microscope revealed disseminated malignant disease. In our patient the lack of knowledge of the malignant changes in the previously removed cyst, together with the lapse of time between its removal and the development of acute symptoms, led us into error.

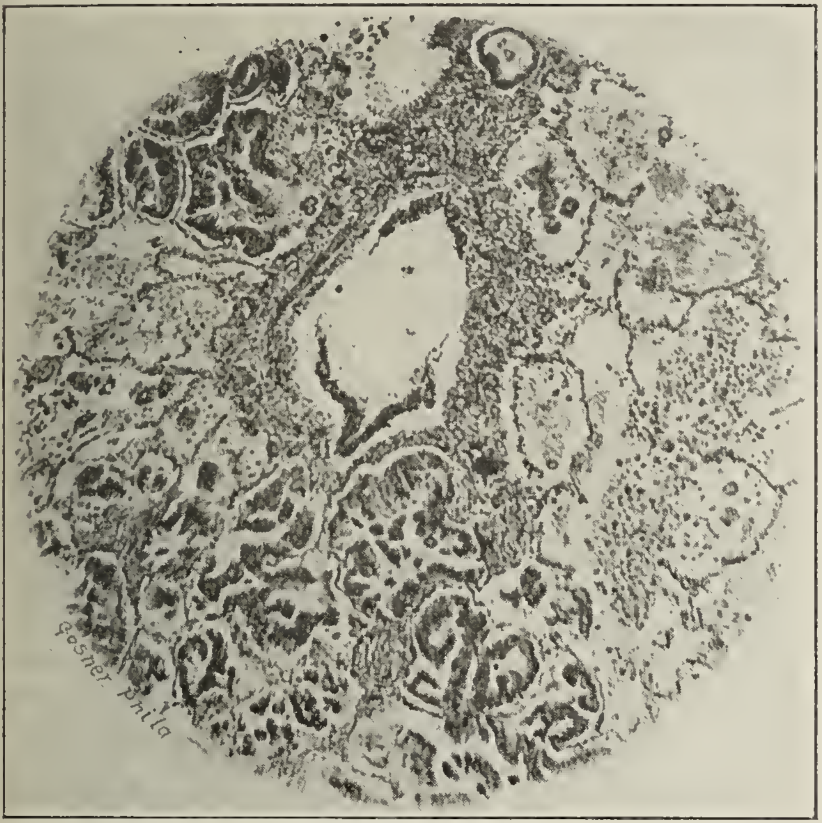

Fig. 3.—A section of the lungs showing the columnar type of the tumor cell; the attempt at acinus formation is very evident. The tumor cells are crowding the air spaces.

Schmidt (7) reports two cases of miliary carcinosis in one of which the correct diagnosis was made during life. The first patient, a woman of thirty-six years, had symptoms suggesting miliary tuberculosis. The normal lung findings, afebrile course and negative diazo reaction were taken as evidence against the diagnosis of miliary tuberculosis. The intense dyspnea and the presence of enlarged lymph nodes in the left supraclavicular region suggested malignant disease. Death in two months with necropsy studies revealed miliary carcinosis. In the second case the carcinosis was assumed during life and postmortem to be miliary tuberculosis until the microscope revealed the carcinosis. In both patients a small cancer was found in the stomach and Schmidt thinks that this is generally the rule, i. e., minute primary cancer plus greater tendency to metastases, large primary cancer with less generalized metastasis. Among nine patients which Schmidt gathered from the literature the age incidence varied from twenty-three to thirty-six years, except one aged seventy-four years. He concludes that miliary carcinosis affects mostly young individuals. Our patient was twenty-eight years of age.

SUMMARY.

1. A case report of miliary carcinosis.
2. Twice during the life of a female of twenty-eight years an incorrect diagnosis of tuberculosis was made. Upon the first occasion tuberculous peritonitis proved by operation to be an ovarian cyst. Twentv months later an acute illness diagnosed by us as acute tuberculosis proved by necropsy to be miliary carcinosis.

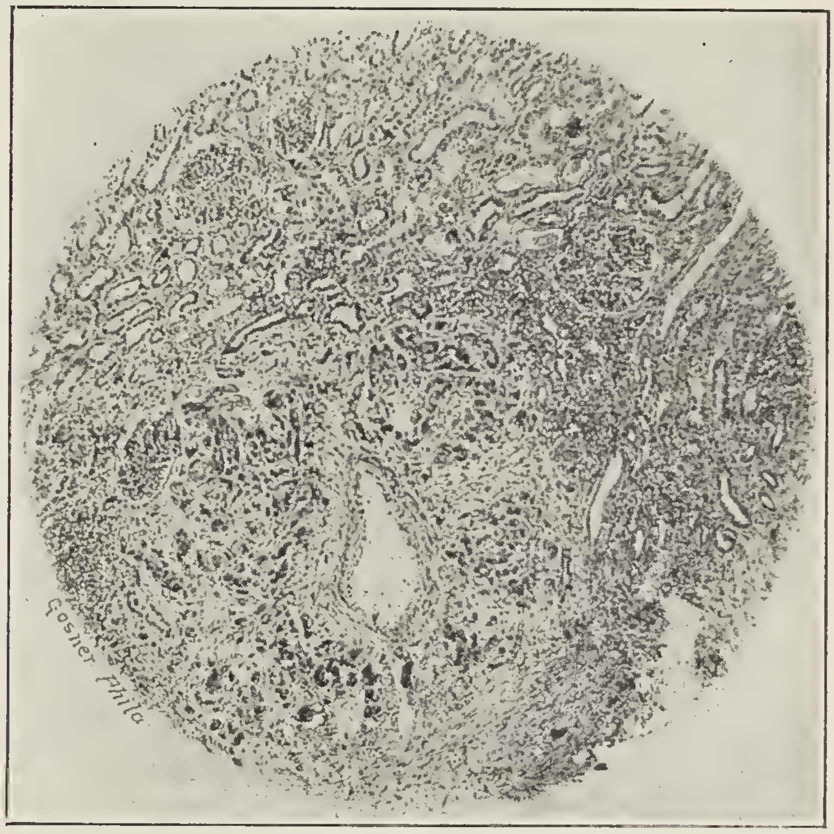

Fig. 4.—A section of the kidney showing small metastatic lesion.

3. The delayed study of the ovarian cyst speci-

men showed the probable primary focus, an adenocarcinoma in the cyst wall, thereby linking up the first and second illnesses wrongly diagnosed as tuberculosis.

4. The delayed and subsequently acute metastases probably resulted from invasion of the blood stream by way of the thoracic duct.

5. The long interval between the removal of the malignant ovarian tumor and the dissemination of the secondary growths. It was evident from the small size of the nodules in the various organs, that dissemination must have been quite recent. We are unable to explain what factors determined the latency of the tumor cells and then their sudden invasion of the blood stream; or the freedom from involvement of the peritoneum which is so frequently the site for secondary growths from this type of ovarian tumor.

The Significance of Gastrointestinal Disturbances in Early Pulmonary Tuberculosis

By S. A. SAVITZ, M.D.,
Philadelphia,
Associate in Therapeutics, Temple University.

The rôle of the gastrointestinal tract in nearly all of the acute infectious and contagious diseases is well known. Influenza, pneumonia, cerebrospinal meningitis, typhoid fever and many other infectious diseases, often begin with gastrointestinal symptoms prior to any other clinical manifestation of diagnostic value. Pulmonary tuberculosis is no exception. So far we have been unsuccessful in recognizing any of the important clinical signs upon the entrance of the tubercle bacilli in the body. If this were possible the mortality of pulmonary tuberculosis could be reduced to a minimum. Some years ago, when the tuberculin tests became popular it was thought that ultimately this disease would be early recognized. Inasmuch as physical signs are usually prominent when one or more of the tuberculin tests are positive, we are handicapped now as never before. No one will deny that cases cannot be classed in the incipient stage when physical signs are clearly demonstrable. The presentation of a paper on this subject should be welcomed, in spite of the fact that nothing original is offered. The little we know about this subject is in my opinion not sufficiently emphasized and we are justified in presenting conjectures and theories relative to this subject.

Among symptoms applicable to pulmonary tuberculosis that of the gastrointestinal tract is important. One of the first symptoms which seems to attract but little attention not only by the patient but also by the physician is anorexia. When this exists for some time the vitality is undoubtedly affected. Insufficient food for a prolonged period will weaken the patient by reason of undernourishment and hence diminish the resisting power considerably. A slightly coated tongue, often constipation, occasional diarrhea, a sense of fullness and depressed feeling after eating, are conditions which may exist for a long time. Hyperacidity, with its epigastric discomfort may be the first manifestation. The more one studies this disease the more attention should be directed to the numerous modes of onset encountered. In one case a simple dyspepsia may be present, in another typical hyperchlorhydria, and in a number nausea; and on examination a pathological condition is often found in one or both lungs. Loss of weight, plus a history of digestive disorders, should be looked upon with suspicion.

Tuberculosis of the stomach and viscera are common but in the majority of cases is either secondary or complicated by a preexisting pulmonary tuberculosis. A reversed condition, pulmonary tuberculosis secondary to that of the stomach, is not probable. Until the last decade tuberculosis of the abdominal viscera remained almost entirely within the domain of the pathologist. The surgeon, long before the internist, attempted to place definite symptomatology relative to the diagnosis of abdominal tuberculosis by demonstrated lesions heretofore discredited. In 1886, Joseph Coates (1) first discovered the tubercle bacilli in a gastric ulcer. Lava and Orlandi (2) told of the failure to find tuberculous lesions in the lungs or in any of the organs in cases of ulcer where the bacillus was isolated.

Infection in gastrointestinal tuberculosis was thought to occur through the tubercle bacilli being taken with food or swallowed with the sputum. Recent investigators proved that in the majority of cases it is through an extension of infection from another organ and also possibly through the blood stream. The latter theory is more plausible because of the fact that the normal gastric juice furnishes a certain amount of protection against the tubercle bacilli; although it has no specific bactericidal qualities. In short, there are sufficient physiological reasons why the alimentary tract has a great resistance to tubercle infection, unless there are sufficient alterations in the normal acidity of the gastric juices.

Pain in the region of the stomach, anorexia, occasional vomiting of blood and diarrhea are a set of symptoms, while not sufficiently distinctive, are nevertheless suggestive. Hotchkins (3) states that gastric analysis helps one to a more definite conclusion, inasmuch as in early tuberculosis an increased acidity exists which is undoubtedly due to a reflex origin. It is well to bear in mind that in the later stages of the disease the opposite condition usually exists, that is, a deficiency in the hydrochloric acid.

F. M. Pottenger (4) explains the origin of the gastrointestinal phenomena in pulmonary tuberculosis. I value his physiological explanation so highly that it would not be amiss to mention just what he said. "The embryological origin of the respiratory system from a diverticulum of the gastrointestinal canal, gives to the lung the same double innervation as that of the intestinal tract. All smooth musculature and all secreting glands of the lung and bronchi, like those of the stomach and intestines (except the sphincters) are activated by the vagus nerves and inhibited by the sympathetic. When the lung is inflamed, the sensory fibres of the pulmonary branches of the vagus are irritated and this produces a reflex stimulation of the motor neurons of the vagus which supply the gastrointestinal canal. The common gastrointestinal symptoms typical of preponderating vagus stimulation are nausea, vomiting, hyperchlorhydria, gastric supermotility, colicky pains, spastic conditions of the intestines, notably spastic constipation, colitis, diarrhea and intestinal stasis. It is this group of functional disturbances that is found most frequently in patients suffering from early active or chronic semiquiescent tuberculosis."

T. A. Groover and A. C. Christie (5) report that in an analysis of 1300 cases referred for gastrointestinal study, six and a half per cent. were tuberculous. The gastrointestinal symptoms in all cases were secondary. A number with early lesions were found but strange to say out of the six and a half per cent. reported the majority showed lesions of a chronic slowly progressive type. Ernest H. Gaither (6) in his article points out that in a number of cases which were presented at the Johns Hopkins Dispensary, the patients exhibited none but purely digestive complaints, that is, loss of appetite, pyrosis, fullness, distress, at times pains in the epigastrium, flatulence and numerous other disturbances. These patients, after a careful investigation, were found to be suffering from pulmonary tuberculosis and not infrequently a cavity formation already existed.

In conclusion I would like to reiterate that it is important to bear in mind that transference of signs and symptoms in any disease is common. How often has a diagnosis of appendicitis been made when the patient had pneumonia? How often has acute indigestion been mistaken for acute dilatation of the heart? And so we may continue to enumerate example after example to show how frequently a mistaken diagnosis may be made. Surely it is imperative, as I have already stated elsewhere (7), that a close survey of all the symptoms necessary and a thorough physical, analytical and fluroscopic examination be done to make an early diagnosis. It is my opinion that a specific for tuberculosis is far from being in sight, and so far our only available weapon in checking the spread of the disease is early diagnosis.

A Preliminary Study of the Antibody Relationship of Members of the Streptococcus and Bacillus Coli Groups*

By JOHN F. ANDERSON, M.D.,
and EMILY B. ELLINGER, A.B.,
New Brunswick, N. J.

As a part of the comprehensive research being conducted by Dr. Henry A. Cotton, medical director of the New Jersey State Hospital for the Insane, at Trenton, N. J., into the influence of focal infections on mental disturbances, it has been necessary to make a large number of cultures from stomach washings. Cultures have also been made from material from other sources, such as tonsils, teeth and lymph glands. The organisms most frequently found have been various types of streptococci, colon bacilli, and staphylococci.

For certain reasons attention has to a large extent been focussed on the streptococci and colon bacilli and vaccines prepared from members of these groups have been used on rather an extensive scale. These vaccines in part have been prepared from stock strains and in part have been autogenous. The question arose as to the nature of the immunity that patients would get from these vaccines. Provided there was antibody production, the stock vaccines might not produce immunity against every strain of streptococcus and colon bacillus; there might be sites of infection missed in getting organisms for autogenous vaccines.

To begin an answer to the question, the following work was done. Two rabbits each were immunized against two strains of streptococci, Streptococcus pyogenes and Streptococcus salivarius; and two rabbits each, against two strains of colon bacilli. By means of complement fixation and agglutination tests, and testing each rabbit's serum against each of the four organisms, an attempt was made to find to what extent the antibodies formed were specific or common. The scope of the work so far done does not justify a detailed review of the literature on similar work.

The procedure was as follows: Rabbits weighing about 2,500 grams were used. They were injected subcutaneously over the abdomen. The four antigens for the injecting were prepared as follows: The thirty-six hour growth from ten large agar slants of Streptococcus pyogenes 721 T was suspended in about fifty c. c. of .4 per cent. tricresolized physiological saline and killed by heating in a waterbath at 56° C. for twenty-five minutes. This streptococcus was obtained from the tonsil of a patient at the hospital. It is a rather large, gram positive, short chained hemolytic coccus that forms acid on salicin and lactose and no acid in mannit sugar free agar in forty-eight hours' growth. It sediments in bouillon. With the Streptococcus salivarius antigen twelve large agar slants were used. Otherwise the procedure was the same as with the pyogenes antigen. The salivarius culture was obtained from a patient at the hospital. It is a small, gram positive, short chained nonhemolytic coccus that forms acid on lactose, no acid on salicon, and mannit sugar free agar in forty-eight hours' incubation. There is a cloudy growth throughout the bouillon cultures.

---

*From the Research Laboratory, New Jersey State Hospital for Insane, Trenton, N. J.

These two streptococci were typed according to the classification of streptococci, by W. L. Holman (1). For the two colon bacillus antigens, Bacillus coli communior and Bacillus acidi lactici, the growth from three large agar slants was used for each culture. The procedure was the same as with the streptococcus antigens except that the killing was by heating in a waterbath at 60° C. for one hour. Both the colon bacilli cultures have been described by C. E. Winslow in Studies on the Classification of the Colon Typhoid Group of Bacteria with Special Reference to Their Fermentative Reactions (2), and obtained from the collection then in New York at the American Museum of Natural History. Bacillus coli communior is a medium sized, gram negative bacillus with small transparent colonies on agar plates. It gives a positive indol test, forms acid and gas in lactose and sucrose, no acid nor gas in salicin sugar free agar. It has a cloudy growth throughout bouillon. Bacillus acidi lactici is a pleomorphic gram negative bacillus with large transparent colonies on agar plates. It gives a positive indol test. It forms acid and gas in lactose, no acid nor gas in salicin and sucrose sugar free agar. It sediments in bouillon to some extent and forms a pellicle at times.

Four of the rabbits, one for each of the four above mentioned organisms, were treated with gradually increasing doses of antigen over a period of about four months. These were: Streptococcus pyogenes rabbit No. 85, received 74.5 c. c. of the antigen; Streptococcus salivarius rabbit No. 18, received 68.5 c. c. of the antigen; Bacillus coli communior rabbit No. 72, received 80.5 c. c. of the antigen, and Bacillus acidi lactici rabbit No. 54, received 79 c. c. of the antigen. Four others, one on each of the test organisms, were treated in the same way over a period of about two months. These were: Streptococcus pyogenes rabbit No. 61, received 41.5 c. c. of the antigen; Streptococcus salivarius rabbit No. 43, received 43.5 c. c. of the antigen; Bacillus colicommunior rabbit No. 96, received 33.5 c. c. of the antigen, and Bacillus acidi lactici rabbit No. 29, received 39.5 c. c. of the antigen. Four days before the final tests and two weeks after the last injection, the animals, with one exception, and a normal rabbit for control, were bled out, the serum obtained inactivated at 55° C. for twenty minutes and .5 per cent. chloroform added. The one exception was Streptococcus pyogenes rabbit No. 85 which died. Serum of this rabbit collected ten days before the final tests and thirteen days after the last injection was used in the final tests. It had no preservative added and was inactivated at 55° C. for twenty minutes. The serum as described above was used in making the complement fixation tests and agglutination tests together with some anticolon bacillus streptococcus horse serum.

COMPLEMENT FIXATION TESTS.

Method.—Antigens were all less than a week old. They were killed suspensions of pure twenty-four to forty-eight hour agar slant cultures of the respective organisms in physiological saline. The streptococci were killed by heating in a waterbath at 56° C. for twenty-five minutes. The colon bacilli were killed by heating in a waterbath at 60° C. for one hour. Before using, the antigens were filtered through several thicknesses of gauze to remove clumps. They were titrated with the hemolytic system reagents used in making the tests and one half the anticomplementary unit was used as the dose of antigen.

The setup for the tests was: .1 c. c. serum dilution; .7 c. c. antigen dilution, and .1 c. c. guineapig complement. The tests were placed in the waterbath at 37.5° C. for one hour. Then .1 c. c. sensitized sheep red blood cells, a 2.5 per cent. suspension of packed cells, added. After another hour at 37.5° C. in the waterbath, the tests were placed in the icebox overnight and read in the morning. Readings were recorded as follows: ++++ complete fixation; +++ almost complete; ++ fixation; + small amount of fixation; ± few red blood cells in bottom of tube; — negative. The hemolytic system, serum and antigen controls were all negative. There was no hemolysis in the corpuscle control. These controls were run in duplicate.

AGGLUTINATION TESTS.

Method.—The antigens were saline suspensions of pure twenty-four to forty-eight hour agar slant cultures of the respective organisms, emulsified with glass beads, filtered through gauze to remove clumps, and contained about one billion organisms to the c. c. The setup of the tests was: .5 c. c. serum dilution, and .5 c. c. antigen. The tests were placed in the incubator at 37.5° C. overnight and readings then recorded as follows: ∏∏ complete agglutination; |∏ almost complete; ∏ partial; | few agglutinated; + doubtful; — negative. Antigen controls were run in duplicate. They were negative with the exception of the Streptococcus pyogenes antigen. Since it agglutinated spontaneously the tests with it were not read.

SUMMARY.

There was practically no common complement fixing body or agglutinin production by members of the streptococcus and members of the colon bacillus groups. Streptococcus pyogenes showed little complement fixing body production with results at variance. It had no agglutinin production for Streptococcus salivarius. Streptococcus salivarius showed little complement fixing body production but that was specific. It had fair agglutinin production. Bacillus coli communis showed complement fixing body production more specific for itself than for Bacillus acidi lactici. Its agglutinin production was almost completely specific. Bacillus acidi lactici showed complement fixing body and agglutinin production practically common with Bacillus coli communior.

CONCLUSIONS.

There was practically no common complement fixing body and agglutinin production by members of the streptococcus and members of the colon bacillus groups. The complement fixing body and agglutinin production by Streptococcus pyogenes and Streptococcus salivarius seemed on the whole to be specific. Bacillus coli communis had rather specific complement fixing body and agglutinin production while that of Bacillus acidi lactici was practically common with Bacillus coli communior. Work of this nature using many more strains as antigens should be done.

Repairing the Human Machine

By FREDERIC G. ELTON, M.D.,
New York,
District Director, State Bureau of Rehabilitation.

This is not a plea but a demand for more constructive work on the part of doctors and surgeons in rendering medical and surgical assistance to the injured workmen of this country. If the necessity for the conservation of waste material is admitted; if the economic reasonableness of repairing a machine so it will again produce is granted as good business, then the salvaging of an injured worker who, injured, is waste material and who, as a human being, is the greatest of all machines, demands equal attention.

The necessity for the using of waste material has, for a long time, been admitted, and much that was formerly considered as useless is now used in the manufacture of marketable products.

The first step in the restoration of an injured worker, like that of the soldier, lies in the hands of the doctors and surgeons and, to a large measure, the responsibility for success or failure rests with them. They must come to appreciate that it is not merely a question of saving a life, of sewing up a wound, or amputating several fingers, but of making it possible for the person to live the life after it is saved and again to be selfsupporting.

Physical restoration of the person must be as complete as it is scientifically possible to make it. That the doctor or surgeon either advances or hinders the reestablishment of the injured is shown by experience. The extent to which he has cooperated with those responsible for the person's reemployment, the extent to which he allowed his skill to be guided by a knowledge of the work a man or woman had done and must do, does often show in the result.

Unfortunately, the human machine is sometimes repaired without a thought that the main purpose is to keep it productive and quite often this repair work is done without the mechanic who performs the operation having any knowledge of the work that the particular machine has been doing. Any good mechanic called upon to repair a machine realizes that not only must he make that machine run again, but that he must make it produce the article it was intended to produce. The point is, however, that there is a definite purpose in the repair work which is often lacking in our medical and surgical services.

That this attention is not given is constantly being evidenced among injured workers seeking employment. These examples of lack of proper attention and consideration of the employment possibilities of the injured person might be classified under two headings, poor surgery and lack of proper appreciation of the fact that the person must work and the operation must be performed so as to make adjustments that will assist him in working rather than hinder him.

As examples of poor surgery we have the young man who fractured his right arm about two inches above the elbow joint. The arm was set improperly so that the forearm could not be raised above a horizontal position. It is clear that there was no thought given to this machine being made even to run, let alone perform some particular work. A second operation was necessary several years afterward and the fractured bone in the upper arm was chiseled away so that the hand could be brought again to the shoulder.

Another is that of a man who had injured his wrist in cranking an automobile. He went to his family physician who told him the wrist was not broken, but merely sprained. After eight weeks' treatment for a sprain, the wrist was finally x rayed and showed that it had been broken.

Still another is that of a man who had a double fracture of the right ankle, caused by being thrown from an express wagon. He was taken to a hospital, but for some reason was sent home without having had anything done to him. During the night the pain was so great that his private physician was called to set the bones and placed the leg in a plaster cast. The doctor of the insurance carrier, calling the next day and finding the leg in a plaster cast, did nothing. Four months later, when the cast was removed, it was shown that the bone had been improperly set. The result was that the right leg was about one inch shorter than the other and the man suffered considerable pain. He can walk only short distances and cannot stand for any length of time.

Then we have examples of the second class which show that operations were not performed with the idea of making possible the person's return to some particular occupation.

The carpenter, having put his right hand in the way of a circular saw, received an injury which resulted in the loss of the index finger, the middle finger and the upper part of the third finger of his right hand. The thumb was badly cut at its base. The operation was performed upon this man with no attention being given to his occupation. The thumb was removed although the man protested against it. It could have been saved and the only reason given for its removal was that infection might have set in. In amputating the middle finger, a portion of the bone near the knuckle was left protruding beyond the hand, while the third finger was allowed to heal in a rigid position. Consideration of what might have been done for this man in the light of his occupation shows that if the thumb had been left on the hand, the third finger treated so that it could be flexed and the protrusion of the second finger had been removed, the man could have successfully handled his tools and returned to his old job. However, the thumb being removed and the stump left, we find that if the protrusion of the second finger had been removed and the third finger properly treated, the man would have still been able to use this finger and the stump of the thumb to pick up things and hold them in his hand. In his present condition, however, his hand is practically useless to him. It is evident that not much thought was given to the operation of the machine nor the particular product that that machine had been called upon to make.

A young woman, working in a laundry, had her hand crushed in a mangle. The little finger was permitted to heal in a rigid position, slightly bent, so that it was continually in her way. From an occupational viewpoint it would have been far better to have amputated it at the second joint, but apparently the surgeon was primarily interested in preserving the fingers regardless of their purpose and usefulness.

A similar condition is recalled of a man who had a rigid index finger and the second finger had been permitted to heal in a rigid position overlapping the index finger, a condition decidedly detrimental to any kind of work in which he might be employed. An operation was performed upon this man whereby the second finger was placed in its proper position and by the transposing of tendons, the flexion and movement of both fingers was obtained.

These examples show the necessity for emphasizing the point that our doctors and surgeons must give greater consideration to the problem of living rather than to the problem of saving a life and tying up a wound. Too much importance cannot be given to the part that good or bad physical restoration plays in the rehabilitation of the injured worker. The responsibility for doing their part towards the successful completion of any rehabilitation program of the injured worker, that first step, intelligent industrial physical restoration, is squarely on the doctors' and surgeons' shoulders and they must accept it.

Why Does Not Prohibition Prohibit?

By S. DANA HUBBARD, M. D.,
New York.

Is the Eighteenth Amendment to our Constitution, enforced through the Volstead Act, supported by the various and individual State Acts of enforcement, successful today in solving the intoxicating beverage problem? I have asked myself this question and have kept my ear to the ground, like the farmer who comes to town to learns the news, and I still hesitate to reach a conclusion. Prohibition has solved the problem for those who have gone the wood alcohol route, the synthetic gin route, the poisoned whiskey route. These lives have paid a dear price and as a man I pity their untimely ending. I am not heartless enough, to think even for a moment, that they deserved their fate because they violated this law. No! A thousand times NO. We Americans have so many laws that it is impossible not to break one almost daily. If you drive an automobile you violate the law time and again. In the same manner, if we prohibit, by statute, "the manufacture, sale or transportation of intoxicating liquors," we make a law that, through legal interpretation is impossible not to break.

The Eighteenth Amendment reads:

> The manufacture, sale or transportation of intoxicating liquors within, the importation thereof into, or the exportation thereof from the United States, and all territory subject to the jurisdiction thereof for beverage purposes is hereby prohibited.

The language is simple, but far from plain.

It would appear that it was the intention of the framers of this statute to prohibit intoxicating liquors for beverage purposes in the United States. If one has ever attempted to write law, or to state in a few words something that affected a great many people, he will find that English is at best a difficult and trying language. Our foreign friends ask, What do you mean? They learn our language from tutors and books and then come here and find that neither can they make themselves understood nor can they understand us. In thinking one's way through the prohibition problem one must be careful, cool and considerate. Nowhere is judicial calm more necessary.

The Eighteenth Amendment to the Constitution is enforced by a Federal law known popularly as the Volstead law. The law was enacted by the process prescribed by the Constitution. No referendum was taken for the reason that no referendum is provided for by the Constitution. This amendment was adopted in precisely the same way in which the previous seventeen amendments were adopted.

So much for legal regularity.

Some people say "they put one over on us," another says "I had no voice in the making of this law and so I do not have to stand for it." Now my friends, all of you who can read, know that this law was debated as early as 1913, when in Columbus, Ohio, a movement was launched in behalf of National Prohibition. All through 1915 and 1916 this subject was debated in church and platform throughout this country from every point of the compass and almost continuously discussed by the press.

HISTORICAL FACTS.

About fifty-three years ago the Prohibition Party was formed. About forty-nine years ago the W. C. T. U. was organized. It was about twenty-nine years ago that the Antisaloon League began its work. The State of Maine adopted prohibition in 1851, Kansas in 1880, North Dakota in 1889, and Georgia in 1907. By their own acts thirty-three states voted prohibition as a state policy before National Prohibition was adopted. Before prohibition was nationally adopted the balance of fifteen states saw an added ten join these ranks. In 1918 there were 3,030 counties in the United States and of these 2,392 had voted "dry!" These records no doubt show to any open mind what a good many of our voters actually think on this question from a political point of view.

HOW WAS THIS AMENDMENT ACHIEVED.

This is an important question, because it is by knowing "when and why" it is expected to determine what part of our people are behind this regulation.

The resolution submitting the amendment to the states was passed by the United States Senate on August 1, 1917, and by the House on December 17, 1917. The Senate voted sixty-five to twenty; the house voted 282 to 128. Forty-six of the forty-eight states have now ratified the amendment. In forty-five state legislatures the total vote for ratification was 1,288 for to 213 against in senates, while in the houses the vote for was 3,739 to 934 against. Thirty-six legislatures are required for ratification.

So much for the economics of the situation. Now for the civics. Who did this? There are those who have analyzed the situation and are of the opinion that it was as usual, "the intelligent minority," who through publicity and money put it over. Who are the intelligent minority? If reading puts light on this subject I would indict all men and women behind big business. This includes life insurance interests, scientists, philanthropists, college men, physicians, teachers, public health officials, welfare workers, railway interests, mining interests, many important industrial groups, and lastly our churches and their allied helpers. Such are the facts as given in our statistics, our press, and our class journals. Informed and intelligent persons, believing in a democracy, a government "for, of, and by the people," know that what can be made legal by a due process, if a mistake has been made, can be amended or repealed, if necessary, to meet the wishes of the majority of those governed.

ASPECTS OF THE PRESENT DAY LIQUOR PROBLEM.

As a preface to this consideration, we will refer to our text "Why Prohibition does not Prohibit," because, in our experience, statistically and circumstantially, here and elsewhere, in this country, my conclusion is that so far prohibition has not prohibited and I am desirous of learning the reason why.

Will national prohibition prevent alcoholic indulgence? The answer is probably best given by asking if State prohibition has stopped alcoholic indulgence? We have shown here that prohibition has been on trial since 1851, and that thirty-three states voted prohibition before the adoption of national prohibition. What have been the consequences?

Prefacing our argument, let us be fair and state that as yet the machinery of enforcement and the education of the people have not been adjusted to this novel requirement. Men with will power and brains correct and check bad habits as early as indications show that such practice is bad. Others do not lend themselves to correction so quickly. The feebleminded person has will power materially impaired and cannot break evil or vicious habits. The saloon has been closed. The beer and whiskey signs have been painted over. But we are informed that though the statute is on the books, and there are some officials trying to enforce the statute, and some courts are puzzling over interpretations of the language, anyone anywhere who has the price and knows "the ropes"—because it is not done openly—can get liquor. This I am sorry to have to state publicly is also the national situation. The statistics of enforcement clearly demonstrate that liquor can be had today, three years after the initiation of this regulation.

The national government operates on a fiscal year, July 1st to July 1st. Today, the newspapers inform us that there are pending 68,562 prohibition cases in the Federal courts alone. In addition there are many more thousands of cases in state and municipal courts. Comparison of annual reports show heavy increases of such cases instead of a reduction, which would be the reaction if the public were inclined to cooperate with this regulation. If this proportion continues, "it will be—as one of our wits, recently remarked—more fashionable to be on the inside looking out than on the outside looking in." (Meaning of course a jail.)

The prohibition bureau turned into the treasury a total of $4,804,271.95 for fines collected in a year; 35,469 persons have been indicted for violation of this act. Such wholesale deviations from the spirit and intent of this regulation are not indicative of cordial cooperation.

The experience of the department of health is shown in the following table:

REPORTED DEATHS FROM ALCOHOLISM.

Year	*Alcoholism*	*Wood alcoholism*	*Acute alcohol poisoning*	*Total*
1910	621	6	8	635
1911	636	6	2	644
1912	570	4	3	577
1913	656	3	2	661
1914	660	5	0	665
1915	562	1	2	565
1916	687	2	1	690
1917	560	8	2	570
1918	252	4	1	257
1919*	176	38	1	*215
1920	98	29	0	127
1921	119	14	8	141
1922	272	15	8	295

*The first year of national prohibition.

Interpretation.—The yearly experience total shows a gradual reduction with occasional increases. In 1918 the year prior to the prohibiting amendment was the best of the series. In 1919 and 1920 the reductions were attributed to the amendment. The sharp rise in 1922 is disquieting. This total is actually greater than that of 1918 prior to national prohibition. The totals for wood alcohol indicts prohibition as not in a single prior year was there an approximation of such an experience as was had in any of the years of prohibition.

The following table gives the number of admissions of cases of alcoholism in the city hospitals:

Year	*Bellevue Hospital*	*Kings County Hospital*	*Total*
1918	728	1,030	1,758
1919	623	736	1,359
1920	390	651	1,141
1921	2,503	842	3,345
1922	4,083	1,541	5,624

The Commissioner of Health sent out a questionnaire to every hospital in New York city asking for a report on the number of admissions to their wards for the previous five years where a diagnosis of alcoholism had been made on any patient. Twenty-nine hospitals responded, reporting as follows:

	Total	
1918	5,710	
1919	4,877	
1920	3,941	
1921	4,338	
1922	6,869	Aggregate 25,735

The figures show an increase in the number of cases of alcoholism in all the institutions specified of fifty per cent. over the figures for 1921, more than seventy per cent. over 1920: forty per cent. over 1919 and twenty per cent. over 1918.

The total arrests for drunkenness reported by Police Commissioner in New York, are as follows:

1918	5,323
1919	5,562
1920	5,936
1921	6,237
1922	7,866

This five year period shows that the lowest number reported by the police commissioner was in the year prior to prohibition. Since this period there has been an ascending amount year by year. The year 1922 showing a forty-seven per cent. increase over 1918.

WHAT IS THE ATTITUDE OF THE MEDICAL PROFESSION.

Medical men have been sorely tried by this regulation. A cursory reading of the amendment, one would think, would show that the manufacture, sale or transportation of intoxicating liquors for beverage purposes, was not in any way connected with the healing art. How, and by what argument, public officials interpreted this law to apply to the practice of medicine is beyond my powers of comprehension. But they have, and have established the most complex and time consuming regulations regarding medicine and alcohol that is annoying, interfering, and preventing proper practice. The largest group of physicians—the American Medical Association—through its house of delegates went on record relating to the attitude of medicine in reference to alcohol and healing. Later a questionnaire sent to a large number of doctors in active practice showed by a small majority, fifty-one per cent. to forty-nine per cent. that physicians considered whiskey a necessary therapeutic remedy. We are informed by the press through the director of prohibition that in New York State there were 12,500 physicians holding permits to prescribe whiskey in 1921. There were 15,602 doctors duly registered in this territory at this time. During this period twenty per cent. of the prescription blanks furnished physicians for prescribing alcohol for the sick were used. This is an average of seventy-six prescriptions for alcohol out of an allottment of four hundred a year for each doctor.

This is an eloquent reply to the question of medical cooperation in the face of the most bedeviling regulations. Physicians as a class dislike and oppose anything that restricts their best intentions in the treatment of their patients, and they nevertheless are in duty bound to encourage and aid in the proper enforcement of all laws.

BOOTLEGGING, ILLICIT IMPORTATION AND SALE.

The Eighteenth Amendment has occasioned a vast army of illict traders in alcoholic beverages, perhaps the greatest in history. If personal experience is an indication of the vastness of the extent, it may be multiplied in imagination *ad lib.* England charges a tax of two dollars on each gallon of liquor exported. The press informs us that there was exported to the Bahamas one million, two hundred thousand gallons last year. Recently there was arrested a man known as the king of the bootleggers. It was openly stated that this alien, of a few years' residence had amassed a fortune of several millions. A bootblack in a village on Long Island, openly exposed in a barber shop sixteen one thousand dollar bills. Grapes which formerly went into grape juice—the unfermented kind—sold in the market for $75 a ton. Last season grapes brought as high as $350 a ton.

Instead of public house—saloon—indulgence today we have home drinking. There has been noticed in many localities an increase in school absentees, in cases of incorrigibility, and a marked increase in drinking and hip toting among young people, who evidently think it smart. It is well known that children are great imitators and have the habit of mimicking their elders, and these innocent little ones think this drinking is mannish and smart. Sad to relate, immoderate indulgence by the youthful leads to many unpleasant conditions. Promiscuous relations are embarrassing and our officials report an increasing number of children born out of wedlock.

And so on and on *ad infinitum,* but these reactions are to be expected under present unfortunate conditions which have been brought about by opposition to this amendment. The naturalist and trainer knows that to accomplish anything in training animals, a little progress should be made, time after time. Now the prohibitionist could not stand for abolishing hard liquor or taxing it out of existence, but extremist that he is, takes his unpleasant medicine all at one gulp, with the natural reaction that an unprepared stomach rejects an overdose. The public would have no doubt stood for a partial regulation, but an absolute annihilation was attempted, and instead of the result desired by all intelligent and thinking individuals, opposition and abuse were the result. Not only opposition and abuse of this one act but prominent men, the press, in lecture and in news, inform us that all law is brought into disrepute. Crime is certainly on the increase.

A final indictment, in this locality at least, is that prohibition appears to have shifted a normal ninety-five per cent. beer drinking population to a hard liquor group. May we not here ask, if this is permitted to continue, what will be the effect on our public health?

WHY DOES PROHIBITION BY STATUTE FAIL TO SOLVE THIS PROBLEM?

Governments cannot improve man. It is the task of man to improve governments. Every attempt to improve morality by law is productive of disorder. Temperance cannot be made possible by statute. Temperance cannot be bought. Legislation often fails. Education never does. There is one safe, sure way to make progress, moral progress at least, and that is, through the hearts of informed men and women. Perfection is a priceless possession and good conduct is the characteristic of the intelligent. Dr. Brookfield, an ardent advocate of temperance in England remarked on this subject in 1841—it was true then, it is true today—"Temperance, you know, is not abstemiousness (prohibition) but well proportioned use of things."

The one simple fact is positive—legislation covering drinking of intoxicating beverages is not going to be respected and public statute is helpful in government only so far as it is respected and willingly supported by public opinion and absolutely no further.

CONCLUSIONS.

State wide prohibition has not prohibited and national prohibition is also for this one reason doomed to failure. America is a temperate, intelligent nation and has fought for and loved freedom. Prohibition by statute annihilates personal liberty.

Prohibition fails because the United States is bounded on the north by hard liquor, on the south by liquor, on the west by rum and on the east by no limit.

It may well be doubted whether there is or has been at any time a State in this union in which a majority of the voting population were abstainers or even believers in prohibition as applied to themselves.

Those wanting a drink, will get it, law or no law. The man too lazy to attend church just around the corner will walk five miles to keep a date with his bootlegger.

We have at best but imperfect means of measuring the effect of alcohol on man but prohibition meets its crucial test in asylums, hospitals, prisons, police courts, almshouses, and vital statistics.

The story may not be as plain as the handwriting on the wall but it is written and those intelligent enough to read and reflect know the verdict.

The net results of study so far of this momentous question is that prohibition by statute is not productive of that reaction which most of us desire when we legislate in behalf of betterment of our fellowman. The law, then, is not the answer. Regulation by statute, if it is not too reactionary may help but when we consider our people as compared by their intelligence quotient with other nations a better plan would have been education.

The normal man will never become a drunkard.

The vast majority of our people, ninety-five per cent. are of this type of manhood. The man with the "squint brain" is the potential dipsomaniac, and once the habit is acquired will go through fire and water, in any weather, to get his drink. Let the recognition then between the normal and the abnormal person guide us in our reforms.

Men with unstable or enfeebled intellects are absolutely powerless to resist the impulse to drink. The possible reform that lies nearest to success looks to the right treatment of individuals who are victims of the lust for alcohol.

HOW MAY A COMMUNITY PREVENT POTENTIAL DRUNKARDS?

As a first consideration there must be personal health in order to have good public health. Health is not the effect of a desire; it is won by effort. He who would have health must work for it; wishing will not achieve it. Health is not something that can be bought at the store nor made at the shop. Health must be thought of as an end and as a means for the accomplishment of that which is worth while in life. We can and do often prevent disease. Our vital statistics prove this beyond argument. Diseases, like tuberculosis and syphilis, which cause degeneration of race stock, must be prevented; when existent, they must be controlled. Our race stock has been made by immigration. It can be improved by careful supervision of further immigration and the elimination of the mental and physically unfit.

We must shield the adolescent from alcohol in every form. We must provide substitutes for the "poor man's club," the corner hang out, the club, the saloon, the den. We must develop community interests that add to health, comfort and welfare. There must be prompt, suitable, and adequate punishment to evildoers.

To me, personally, the incidents indicative of the evil consequences of statutory regulation of indulgence in alcohol is but a natural sequence. It was almost prophetic. The committee of fifty scientists reported as an estimate of the percentage of different kinds of indulgers in our population as follows: Abstainers, twenty per cent.; indulge to excess, five per cent.; moderate, fifty per cent.; social, twenty-five per cent.

WHAT PROHIBITION HAS DONE.

1. Prohibition has increased enormously the deaths from wood alcohol.
2. Prohibition has increased admission to general hospitals of cases of alcoholism.
3. Prohibition has made men switch from beer drinking to hard liquor.
4. Prohibition has increased alcoholism in the two alcohol services of our two hospitals.
5. Prohibition has closed the saloon but has made home brewing and occasioned home drinking.
6. Prohibition has increased the wholesale price of grapes, rich in phosphates and vitamines, beyond the price for average home consumption.
7. Prohibition has increased the number of arrests for drunkenness.
8. Prohibition has brought about wholesale disrespect for law.
9. Prohibition has caused poisonous death dealing drinks to be made and sold promiscuously.
10. Prohibition has increased alcoholic indulgence by the adolescent male and female.
11. Prohibition has brought about wholesale bootlegging and illicit peddling of impure liquors.
12. Prohibition has brought an increase in the manufacture of spurious money.
13. Prohibition has brought about "speakeasies" for the sale clandestinely of liquor.
14. Prohibition has many sins, social and hygienic to account for.

These fourteen points are consequences, disappointing in our public health experiences, and are a terrible indictment of such regulation. These facts should make thinking persons consider seriously if this is the right way to deal with the problem. Privileges, that are almost as natural as life itself, being swept ruthlessly away over night, naturally beget an antagonistic reaction which can only be hurtful to a good cause having high aims. Let us reflect.

Editorial Articles

THE MESSAGE OF PSYCHIATRY TO GENERAL MEDICINE

Dr. William A. White in a recent article in *Southern Medicine and Surgery* entitled The Message of Psychiatry to General Medicine gives some wholesome advice and points to some pertinent facts in modern psychiatry. As he states, the path of science leads from the region of the known into the region of the unknown, and study, research and experimentation are necessary and imperative. Whenever a science becomes fixed or final, it ceases to grow, and efforts are spent mainly to uphold and support its established theories, etc. Such has been the case with religion, and until the past decade with psychiatry. But to quote White: "The scientific spirit has invaded the field of psychiatry and in no department of medicine has progress been so rapid or greater strides been made, and today scientific psychiatry, as a medical specialty, is of equal dignity with the other specialties and has attracted many skilled physicians and profound thinkers, yet the majority of medical men realize very inadequately its accomplishments and should be taught by text in journals, and lectures before medical societies its dignity and importance." He admonishes all in studying psychiatry to study the man as a whole—as a total organism, and not merely the brain or mind. The psyche is as old as the soma, and the mind and the body are but different aspects of life itself, and psychiatry has come to realize this concept.

The mind by its ideas, ideals, feelings, emotions, or other symbols represents the tendencies of the individual as a whole—the objects or goals which are desired, or wished to be attained, and the body consists of the machinery by means of which these desires are attained; and the wishes are considerably dependent upon the organic makeup, thus showing the interrelationship of body and mind. White says the habits of life are matters of the mind, and habits materially modify our health, hence correct habits should be early inculcated. Also that organic disorders have their psychological as well as somatic symptomatology, and he gives diabetes as one example in which the patient is suffering from a continuous bombardment of violent emotions, due to the correlation of the emotions with the mobilization of sugar in the body. The mere fact that he does not show violent emotions to the ordinary observer is no more proof that he does not harbor them than that he cannot have a pancreatitis because he does not have a visible sign on the surface.

White says: "If the organism is a unity, if mind is but a name for the functioning of the unity as a whole, then whenever there is any serious organic involvement of part, or parts, of the organism there must be some sort of expression of the trouble in the mind, the psyche; and it will be found if sought for carefully and methodically and with the possible aid of psychoanalysis." We know too little about such large matters as sex, menopause, senility, glandular or endocrine disturbance, metabolism, arteriosclerosis, and the part they play in conditioning various diseases, and psychiatry has something to offer in unravelling these complex problems.

A NEW DISCOVERY

Several discoveries in the sphere of medicine have been made recently. Dr. W. Langdon Brown, of London, one of the first authorities on endocrinology in Europe, writing to the *Lancet,* June 16, 1923, on the question as to whether diabetes mellitus is a progressive disease, holds that it is not so when the proper dietetic measures are used at an early stage of the disease. But in many cases the low caloric value necessary to keep the patient free from hyperglycemia is inadequate to enable him to carry on any tolerable kind of existence and it is here that Dr. Brown thinks insulin comes to the rescue. By its aid the caloric value, especially if derived from protein, fat, and five per cent. vegetables, can be raised to a level compatible with reasonable comfort without producing hyperglycemia. And evidence is accumulating that if insulin is used in this way there is an increase in carbohydrate tolerance. Used otherwise insulin appears to him to be merely an expensive palliative.

Another discovery has just been announced in the realms of socalled vaccine therapy. Professor Georges Dreyer, of Oxford, lecturing on June 14th, at St. Mary's Hospital, London, showed how in some instances bacteria may be so treated by formalin and acetone that their fatty sheath or envelope is dissolved, leaving only a thin part of the body of the bacillus remaining which is not acid fast, is digested more or less easily with trypsin, and will cause the production of various antibodies when inoculated into animals. Prof. Dreyer has pointed out that antibacterial, as distinct from antitoxic immunity, can be obtained better with gram negative than with gram positive organisms, which suggests that the lipoidal substances, on which he believes gram staining to depend, are responsible for the failure of gram positive and acid fast bacilli to arouse an effective response in the body. With these defatted bacteria, it is hoped that results, long vainly hoped for, will be obtained. In fact, experimental animals, seriously infected with tuberculosis, have been cured by the administration of defatted antigen. Moreover, preliminary observations on the treatment of human cases by the same method at the London hospital have been distinctly encouraging. Also, it would seem that other diseases may be dealt with successfully in a similar manner, as defatted preparations have been made with staphylococci, streptococci and other organisms which open a wide field in the therapy of immunology. So far vaccine therapy has met with no striking success either from the viewpoint of preventive or curative medicine and therefore Prof. Dreyer's discovery marks a step in advance; how long a step it is at present impossible to foresee.

Sir Almroth E. Wright has been the chief exponent of vaccination against disease—the pioneer in these methods may perhaps be the more apt term. But he has revised his opinions on the subject, since he set himself to perfect the mode of preventive inoculation against typhoid fever which has been so great a boon to mankind, especially during the years of the war. Sir Almroth has changed his views to the extent he no longer holds that our bodies elaborate a special and specific antidote against each germ which attacks them. He takes the stand that there is stored up in the white cells of the blood a stock of antidotes which can be released with extreme rapidity and which is capable of destroying most of our bacterial enemies. Prof. Dreyer's method of bacteriotherapy, under the specific stimulus of defatted antigen, enables animals infected with tuberculosis to cure themselves or indeed animals infected with certain other disease bearing organisms to effect their own cure.

Medical research has won many triumphs of late and has demonstrated that money spent in this way is indeed money well spent. Perhaps more of the mysteries of disease will be revealed when endocrinology is better known and treatment by glandular products has become a more exact science. A philosopher said the wise man was one who knew how little he knew. The wise investigator is he who is aware of this fact but is always endeavoring to increase his knowledge. The main reason why money is necessary to the research worker is that if he is not free from financial worry and has to work for his living he cannot devote himself with that zeal and wholeheartedness to his work which alone commands success. And further it must be borne in mind that the successful investigator is like the poet, born not made. Pasteur, whose centenary has just been celebrated and who is the father of modern scientific research, is the most striking example of the truth of this statement.

FIFTY YEARS OF HEALTH PROGRESS

In a recent number of *Public Health Reports,* Dr. George M. Kober outlines the several achievements bearing on the conservation of human life and health during the past fifty years. As an introduction to this, he gives a brief history of hygiene and sanitation from the times of the ancient Egyptians, through the plague stricken Middle Ages, down to the achievements of scientific medicine in the present day.

Some interesting figures are given on the life span and mortality rates of the past as compared with the present. It has been estimated that the average length of human life in the sixteenth century was between eighteen and twenty years; at the close of the eighteenth century, it was still less than twenty-five years. At the close of the nineteenth, it was between forty-five and forty-eight years; today it varies in different countries, from less than twenty-five in India to sixty in New Zealand, and fifty-six in this country.

The general mortality rate in the registration area of the United States has been reduced from 19.8 in a thousand in 1880 to 11.6 in a thousand in 1921. This means the saving of about half a million lives for the one year alone. During the year 1875, nearly forty per cent. of all deaths were due to consumption, infant mortality, and smallpox. The death rate from consumption has been reduced from 439 in a hundred thousand in 1876 to 108 in 1922, a saving of approximately fourteen hundred lives for 1922. The infant mortality rate has been reduced from 322 in 1878 to 84.5 in 1922, a saving of about two thousand babies. The typhoid fever death rate has been reduced from eighty-three per one hundred thousand in 1890 to 4.8 in 1922.

These remarkable reductions in mortality rates are due to the fact that fifty years ago we knew little or nothing about infectious or communicable diseases; now we do know a good deal about them. In 1908 it was estimated that about three million persons were sick at all times in the United States, and that forty-two per cent. of this illness was preventable. It was estimated that in 1922 there were two million four hundred thousand continually ill persons and that half the sickness was preventable. During 1917 there were about forty-five thousand fatal accidents, and about 5,625,000 nonfatal injuries caused by public accidents. Probably seventy-five per cent. of this accident rate is preventable.

In closing, Doctor Kober speaks of the fifteen year gain in the span of human life, and declares that he is sufficiently optimistic to believe that, provided we maintain high standards of living and civilization, the average span may reach the biblical three score and ten by 1950. "This, however, can be accomplished only in an uninterrupted period of peace and prosperity; indeed, it is utterly impossible under chaotic political and economic conditions with war and food shortage. We have referred to the sad effects of the Dark Ages on health, and the influence of war and revolution on poverty, famine, and pestilential diseases. God forbid the reenactment of scenes of the Middle Ages, with all the evil consequences on the health, longevity, and happiness of the human race!"

ETIOLOGY AND TREATMENT OF ARTHRITIS

A certain amount of haziness still exists with respect to the etiology of that condition known as arthritis and consequently views as to treatment are not quite so definite as could be desired. Arthritis is a disease which is probably on the increase but is considerably more prevalent in Great Britain than in this country. It is needless to say that there is no more crippling and few more painful diseases known, and it would be to the manifest benefit of the community if its etiology was made clear, as then, of course, treatment would be undertaken on more decided lines than is at present the case.

At a general meeting of the fellows of the Royal Society of Medicine, in London, on April 23d last, the subject discussed was the etiology and treatment of osteoarthritis and rheumatoid arthritis. Sir Archibald Garrod opened the discussion and said in part that chronic articular disease was an obscure branch of medicine, the gross classification and multiple nomenclature of which were sure signs of ignorance. He pointed out that osteoarthritic lesions, erosion of cartilage, eburnation of bone, the formation of osteophytes, etc., developed insidiously in elderly people with a characteristic distribution, quite apart from infective rheumatoid troubles. So far as septic foci were concerned, in the teeth or elsewhere, the part they played was still obscure. Treatment had advanced very little. Drugs generally failed to achieve much. Garrod considered guaiacol carbonate administered over a long period to be most useful. In osteoarthritis drugs were of little use.

Dr. M. Cassidy considered that the importance of infective conditions in the etiology of these diseases, especially in the case of rheumatoid arthritis, had been much overrated. He regarded the latter as a clinical entity, a somewhat uncommon disease and one almost entirely confined to women. Rheumatoid arthritis tended to be hereditary, but Dr. Cassidy's remarks applied only to genuine rheumatoid arthritis. Never in his experience was the relentless course of the disease arrested by extraction of teeth or by inoculation. There was, however, a large group of cases of chronic infective arthritis which might resemble closely the former disease, in which an infective focus was readily demonstrated, and when it was removed gratifying therapeutic results usually followed. He thought that many cases of osteoarthritis were metabolic rather than infective, for instance, those in which the onset in the knees was acute, those with or without Heberden's nodes in the fingers in women at the time of the climacteric. While he was fully alive to the dangers of chronic septic intoxications, perhaps the majority of all cases of chronic polyarthritis were infective, he submitted there were other common, important, and easily recognized types, and he considered it retrograde to lump all these diseases together under the horrible title of nonspecific infective arthritis.

Dr. F. J. Poynton, who holds that he and Dr. A. Paine discovered the cause of rheumatic fever in the shape of a paired coccus to which they gave the name Micrococcus rheumaticus, joined in the discussion. He said that it was over twenty years since he and Dr. A. Paine had demonstrated the experimental production of osteoarthritis with a streptococcus, and rather later they showed experimentally that, 1, the same infection in varying virulence might produce various types of arthritis; 2, that a nonarticular arthritis might result from a blood infection.

The problem of rheumatoid arthritis was unfortunately much more complex. In his opinion it was their lack of knowledge of the life history of infection in the human tissues that was now an obstacle in the treatment of disease. Bowel infection was the most favored theory of causation of the movement. However, he regarded the colitis as an effect rather than a cause of the disease in many cases, and was cautious in advising treatment by colonic douches. Dr. Poynton advocated the employment of vaccines when a pure or almost pure culture could be obtained from an obvious local focus. Organotherapy was helpful in cases at the menopause and those with vasomotor spasm. He avoided the use of radiant heat in cases that were more painful in the summer than in the winter.

It appears to be the general belief that drugs are of little avail in the treatment of arthritis, except in those forms, the gonococcal for example, in which the infective agent is known. The treatment then is to cure the primary infection. In some forms of the disease intestinal antiseptics are advocated. Mouth infection, and especially pyorrhea alveolaris, is not regarded as the chief cause as it was considered a few years ago, and therefore the wholesale extraction of teeth is not now considered to be a *sine qua non* of successful treatment.

PHTHISIS IN THE GRANITE INDUSTRY

The problem of dust phthisis in the granite stone industry has long been of the first importance, from the point of view of both medicine and insurance. Frederick L. Hoffman, LL.D., has completed a detailed study of this problem for the Bureau of Labor Statistics of the United States Department of Labor, which has recently been issued as *Bulletin* 293 of the bureau.

The granite stone workers of Vermont were the subjects of this study. Although these laborers live under sanitary and housing conditions above the average, and are of a superior physique, indicative of a higher degree of resistance, their mortality from pulmonary tuberculosis has increased enormously during the last two years. Every other stonecutting centre of the United States shows the same condition. And this in the face of the facts that the mortality of the population at large is diminishing, and that normally the rate of tuberculosis decreases with increasing adult age. Among granite cutters the death rate from pulmonary tuberculosis at ages of sixty and over "reaches truly appalling proportions, so much so that the statistical evidence would seem incredible if it were not supported by the additional and equally suggestive data for nontuberculous respiratory diseases." These conclusions are in conformity to the observations made in South Africa and Australia.

There are, therefore, clear indications that the cause of this excessive liability to pulmonary tuberculosis is the inhalation of granite dust in a comminuted form of practically ultramicroscopical particles. Unfortunately no autopsy material is as yet available in this country to determine the dust content of the silicotic lung. The evidence is also conclusive that workers exposed to marble or limestone dust are much less liable to pulmonary tuberculosis than those exposed to granite or sandstone dust, with a high silicotic content. There are many reasons for believing that this disease, certified among granite workers as pulmonary tuberculosis, is often not a true form of tuberculosis, but a silicosis or pneumonoconiosis, possibly in its terminal stage complicated by a superinduced tuberculosis. Thus a further conclusion arises that methods of prevention applicable to true tuberculosis will be largely inapplicable to a disease chiefly nontuberculous in origin and frequently in termination. If it is nonbacillary in origin and progress, it cannot be infectious, hence does not constitute a serious menace to adult population.

Doctor Hoffman quotes these, and many other deficiencies in knowledge of the disease, as conclusive evidence of an unfortunate apathy on the part of the medical profession in realizing the difficulties of the question. This industry demands, perhaps more than any other dusty trade, "the utmost and thoroughly qualified consideration on the part of the State, the medical profession, and the labor organizations directly concerned. At the present time the death rate among granite workers is practically the highest known for any occupation of record, and the increase in the death rate from year to year is lamentable evidence of the inefficiency on the part of the health promoting agencies to bring about reduction and control. The problem concerns not only the wage earners, who directly pay a frightful toll in needless deaths and prolonged chronic disease, but the burden also falls, and possibly with crushing weight, upon the industry, which is deprived of skilled workers. The present inquiry should prove of particular value as an indication of new methods by which the facts of industrial health can be determined with practical certainty and at minimum expense. The investigation emphasizes the futility of broad generalizations, in which essential matters of detail are disregarded. . . . The present discussion is intended to reemphasize the industrial aspects of disease along lines of prevention which cannot possibly fail. If the dust hazard is the causative factor in the enormous respiratory disease mortality of granite and other stone workers, and if preventive means are possible by which the dust menace can be brought under control, it is for the State, for the labor organizations, and for the industries concerned to see to it that what can be done about it is done without needless delay."

THE MENACE OF EASTERN EUROPE

The conditions prevailing, at the present time, in Eastern Europe are appalling and constitute a standing menace to the health of the entire civilized world. During the war the state of affairs there was such as to strain the resources and energies of medical men, sanitarians and philanthropists of every description almost to breaking point, to prevent the foul epidemic diseases engendered and developed by filth, from overwhelming Western Europe. It was indeed a triumph for sanitation and hygiene in which Americans played foremost parts, that diseases, some of them imported from Asia, that pest hole of the world, were kept within bounds. It was regarded as a necessary accompaniment of warfare carried on under the conditions which existed, and the real triumph of the war from the medical point of view was as much the successful treatment of wounds and disease as the prevention of epidemics. It was expected that heroic attempts must be made during the war to prevent epidemics and to curtail their spread. The tragedy of the situation rests in the fact that the war has been over for more than four years and yet the conditions of Eastern Europe are a menace to the civilized world. In Poland and nearby countries disease is rampant, but at the present time the principal danger zone is in Greece and to a lesser extent in Turkey, owing to the enforced exodus of thousands of Greeks from places which had been allotted to them by the Allies and from Turkey itself, as one result of the success of the Turkish arms. More than one million refugee Greeks are scattered throughout Greece and naturally when they are not afflicted with epidemic contagious disease, are very susceptible to these diseases, owing to their debilitated state.

In the *Lancet,* March 17, 1923, Sir Patrick Hehir, late major general I. M. S., and an authority on tropical diseases, writes concerning the Greek refugees. At the time he wrote he was traveling in Greece in order to make observations. He points out that the most important measures necessary at the present time are the isolation of all cases of infectious disease and the prevention of the dissemination of these diseases. It appears that cases of typhus fever are sometimes not discovered in refugee camps for a few days after they have become infective. Many of these cases are diagnosed in the early stages as influenza and one group of these wrongly diagnosed cases is said to have infected a whole general hospital. In a few instances individuals suffering from typhus in the preeruptive stage have been discovered walking about with healthy members of camps. Attention is directed to the fact that there seems to be a remarkable difference in the intensity and mortality of typhus in different areas.

It should be mentioned that Sir Patrick Hehir's article is virtually an appeal for help, an appeal, it may be said, to the British, as at present the Americans are taking by far the largest share of this relief work in all its branches. If these people were not helped they would not only die like flies, but they would spread epidemic diseases, chiefly typhus, throughout Greece and probably Eastern Europe, and who can say that the conflagration of disease once well started might not rage over Western Europe and even reach this country. So that it is not only an act of humanity and philanthropy to assist the people of Eastern Europe to fight the diseases attacking them, but a measure of selfinterest to prevent such diseases from spreading far and wide.

The League of Nations is doing yeoman service in Greece. Among other services which its medical representatives are performing is the colossal task of inoculating the whole group of refugees in Greece against enteric, paratyphoid A and B, and cholera, and vaccinating against smallpox. Inoculation against typhus is also being adopted, but as it is more or less in the experimental stage it is voluntary. It is said that there is absolutely no reaction and it is further stated that Dr. George Blanc, *directeur de L'Institut Pasteur Hellenique,* says that he has done thousands of inoculations and has not heard of any inoculated person acquiring the disease, but cannot yet express an opinion as to its prophylactic value.

The object of this editorial is to emphasize the point that conditions existing in Eastern Europe are an indirect menace to the health of the world and that, therefore, it is to the ultimate benefit of everybody that the epidemic diseases rife there should be stamped out, or at any rate prevented from spreading.

CARRIERS OF COMMUNICABLE DISEASES.

In a recent number of the *Public Health Bulletin* on the subject of Communicable Diseases and Travel, Dr. Thomas R. Crowder gives some interesting information on the relation of carriers of communicable diseases. He classifies carriers as active and passive. An active carrier is one who has passed through and recovered from a disease, but who has failed to cast off all of his infecting organisms. In most cases of infectious diseases the patients remain active carriers for a short time after clinical recovery; some remain so for a long time, and a few become permanent or chronic carriers. A passive carrier is one who harbors in his body the virulent organisms of a disease from which he has never suffered any illness—who has become infected, and in whose body the infecting organisms grow, but whose resistance or natural immunity is so high that the infection does not cause development of the disease. Passive carriers are not infrequently found among those who are in close association with an acute case of communicable disease. Like active carriers, they may soon get rid of their germs and return to the normal state; but some continue to harbor and expel dangerous organisms for long periods, and in some instances finally fall victims to the very organisms they have harbored so long without apparent harm. "Although we have not enough evidence to show clearly just what is the relative importance of carriers and of sick persons in the spread of the communicable diseases, there is ample epidemiological evidence that healthy carriers may be the source of well marked outbreaks of some of the most common of them. . . . A practical plan to discover and cure carriers is indeed one of the most urgent needs of sanitary science at this time."

News Items.

Hospitals Observe Their National Day.—National Hospital Day and the anniversary of the birth of Florence Nightingale were observed on May 12th in some of the hospitals either by keeping open house for visitors or by parties for the children.

Curbing Yellow Fever.—Progress in control of yellow fever and hookworm diseases was reported by Dr. George E. Vincent in the second installment of the report of the Rockefeller Foundation, made public recently.

Hospital Care for a Rural Community.—In February last the town of Cuba, Allegany County, N. Y., opened an eighteen bed hospital under the name of the Soldiers' and Sailors' Memorial Hospital. The town has a population of about seventeen hundred.

Hospital Diagnosis Station Transferred.—On July 1st, the Hospital Diagnosis Station, previously located at 128 Prince Street, was transferred to 505 Pearl Street and conjoined with the Corlears Tuberculosis Clinic, under the supervision of Dr. E. L. Creeden, who was designated physicians in charge of Corlears Clinic.

New York City Death Rate.—The death rate for the first twenty-six weeks of the year was 13.55 to a thousand of the population, as compared with 13.71 in the corresponding period of 1922. From January 1st to July 7th seventy-four infants under one year of age died out of every thousand born, as compared with eighty-four deaths in this age group in the corresponding period of 1922, a decrease of ten deaths to a thousand births.

Deaths From Automobile Accidents.—The number of persons reported killed in automobile accidents during the first six months of 1923 was 454, as compared with 458 killed in the first six months of 1922, according to the Bureau of Public Safety of the Police Department. The number of killed showed a decrease, although the number of automobiles in the city had increased. The decrease in fatalities was believed to be largely due to the safety campaign conducted by the bureau among children and drivers of automobiles.

Civil Service Examination for Assistant in Neuropsychiatry.—The United States Civil Service Commission announces an examination to fill a vacancy in the Public Health Service, Boston, Mass., at $1,800 a year, plus the increase of $20 a month granted by Congress; a vacancy in the position of special assistant in neuropsychiatry, Veterans' Bureau, New York City, at $1,800 a year, and vacancies in positions requiring similar qualifications throughout the United States. The receipt of applications for this examination will close August 21st.

Health Scholarships.—A fund of $25,000 to be used as scholarships for teachers best fitted to promote health work in the schools has been donated by the Metropolitan Life Insurance Company, through the American Child Hygiene Association. There will be fifty scholarships of $500 each. Announcement is made that fifteen scholarships have been awarded to teachers who will take summer courses in child health education. Applications will be received by the American Child Hygiene Association up to December 1, 1923.

Negro Death Rate.—The mortality rate among negroes in the United States now is seventeen in a thousand according to statistics collected by Howard University. The figures further show that colored physicians and surgeons have increased 23.7 per cent. in the last ten years.

Royalty to Honor Rockefeller Gift.—As a result of the gift by the Rockefeller Foundation of £1,205,000, the largest sum ever given in England for educational purposes, the University College Hospital will possess the finest laboratories for scientific medicine in England, a thoroughly up to date maternity hospital with sixty beds, and additional medical and surgical wards with 120 beds. The King and Queen will lay the foundation stone of the new hospital buildings and will declare open the new medical research building.

Howard University Endowment Fund Completed.—Announcement is made that the campaign of Howard University, under the jurisdiction of the Department of the Interior, to raise $250,000 to make up a $500,000 endowment for its medical school, half of which was pledged by the General Education Board, has been a success, and an additional $15,000 has been contributed.

Free Dental Clinic Opened in New York.—A free dental clinic, equipped to perform all services from prophylaxis to operations, was formally opened at 327 East 149th Street, under the auspices of the Northern District Dental Society. School children who cannot afford to pay the regular cost of professional services may apply for treatment at the clinic. Four dentists and a trained nurse will be in attendance at all times, the 320 members of the society having volunteered their services free of charge. Five departments have been inaugurated in the clinic, in which demonstrations will be given at regular intervals for dental students. Dr. S. Maggin is chief of the fillings department; Dr. A. Kuntz, chief of prophylaxis and pyorrhea; Dr. M. L. Rosoff, of oral surgery; Dr. M. L. Berger, of x ray, and Dr. S. Herder, of orthodontia.

Personal.—Dr. William Allen Pusey, of Chicago, was elected president-elect of the American Medical Association, at the annual session held recently in San Francisco.

Dr. George A. Soper has been made managing director of the American Society for the Control of Cancer.

Dr. Frederick M. McPhedran, of Toronto, has been appointed assistant in clinical research of the x ray department of the Henry Phipps Institute in Philadelphia.

Dr. Paul A. Lewis, of Philadelphia, for thirteen years director of the laboratory of the Henry Phipps Institute of the University of Philadelphia, has accepted a position at the Rockefeller Institute, Princeton, N. J. He was given a farewell dinner on June 18th by the staff of the laboratory.

Professor Franz Boaz, anthropologist of Columbia University, has been elected to corresponding membership in the Academy of Sciences at Vienna.

Dr. William Darrach, dean of the medical faculty of Columbia University, will represent Columbia University at the celebration of the centenary of the birth of Joseph Leidy, the American naturalist. The meeting will be held in the Academy of Natural Sciences, Philadelphia, on December 6th.

AIX-LES-BAINS

Ancient and Modern

By B. Sherwood-Dunn, M. D.,
Nice, France,
Officer d'Académie, corresponding member Société Obstétrique et Gyynécologique de Paris, Ex-Colonel Medical Corps of the Army.

HISTORICAL.

Aix had its origin in the days of the Allebrogia and the first historical designation was Aqua Allobrogorum, long before the Christian era. The beginning of the present bathing establishment was made when the Roman Consul Domitius, in 122 B. C., built his baths, the ruins of which are still to be seen, from which time the place was given the name of Aqua Domitiana.

Southeastern Gaul (France) was under Roman dominion before the time of Cæsar and it was only after the second expedition of the Roman Legions, in response to the second appeal from the city of Massillia, the modern Marseilles, for aid against neighboring tribes (125 B. C.) that Rome retained her conquest and formed a new dependence between the Rhone and the Alps, later called Provence.

Sextius founded the town of Aqua Sextia as its capital. Soon the Allebroges who occupied the territory now known as Savoie and Dauphine, were conquered, and finally the whole district watered by the Rhone, as far north as Lake Geneva, became an organized dependence of Rome (118 B. C.).

This Transalpine province formed an advanced outpost from which the Roman Senate held in check the tribes of Gaul, forming a base of operation, from which Julius Cæsar finally conquered the whole country, bringing it under the Roman dominion (50 B. C.). She continued the control about five hundred years, which accounts for the numerous arches, ruined temples, and other Roman relics found throughout all of France today.

The earliest records of the Franks, the ancestors of the French, is about two hundred years before the fall of Rome, when they began crossing from the east to the west bank of the Rhine, and settling in what is now Belgium and Northern France.

Their first dynasty was the Merovingian, founded by Meroveus, a king who took part with the Visigoths, Franks and Romans under command of Aetius, in the battle of Chalons (451 A. D.), which was one of the fifteen decisive battles of history. This battle overthrew Attila and his barbarian Huns. and saved civilization to Europe.

Charlemagne was the greatest of all French kings, and on Christmas Day, 800 A. D., was crowned by the Pope in St. Peter's, Rome, Emperor of the Holy Roman Empire, comprising all of Continental Europe. Had he wisely divided up his vast territory, many of the modern wars might have been avoided.

With the dismemberment of the Empire by the Treaty of Verdun, Savoie, in which province Aix-les-Bains is situated, was included in a strip of territory given to his son Lothaire, who was then King of Italy, and it thus became a part of Italy; and has gone back and forth, in its history, between Italy and France, a good deal as Alsace-Lorraine has gone back and forth between France and Germany.

The descendants of the House of Savoie were successively counts, then dukes, then kings of Sardinia, and finally in the nineteenth century kings of Italy and rulers of Savoie.

Not to go too much into the details of history, Savoie, in 1792, during the French Revolution, became a part of France. The majority of the Savoyards were in sympathy with the principles for which the French Revolution stood, and on September 24, 1792, General Montesquiou took peaceful possession of Chambery, the capital of Savoie, and that province remained a part of France for twenty-three years, until the overthrow of Napoleon I, when it again became a part of Italy.

When the Emperor Francis Joseph of Austria invaded Italy, in 1859, he found himself confronted by Napoleon III at the head of a French army. By the combined forces of Italy and France he was promptly defeated, and as a reward for this assistance by the Treaty of Turin, March 24, 1860, Savoie and Nice were ceded to France.

In the fifth century vandalism destroyed many of the old Roman monuments and nothing is known of the history of Aix during the Dark Ages. In the thirteenth century Aix was destroyed by fire and when reconstructed was made into a barony, and in the sixteenth century into a marquisate, when the chateau was built, that is now in use as a Town Hall. In 1776 the King of Sardinia laid the cornerstone of the present Thermal Establishment and inaugurated the era of prosperity that has never ceased.

In recent times it has been a favorite resort of many of the crowned heads of Europe: Victor Emmanuel II, Napoleon III, Queen Victoria and her daughter, Princess Beatrice, Queen Wilhelmina of Holland, King Leopold of Belgium, King George of Greece and Marie, Queen of Roumania.

This resort was discovered to the Americans by Mr. J. Pierpont Morgan, who frequented it regularly, and it was in memory of his favorite physician that he gave the money for the erection of the American Hospital, situated upon the boulevard that bears his name.

SITUATION AND CLIMATE.

The situation of Aix-les-Bains is one of idyllic beauty. It rests in a verdant valley on the border of Lake Bourget, surrounded on all sides by lovely hills and majestic mountains. The town is protected on all sides from the cold blasts of winter, and its elevation of 850 feet renders it free from oppressive heat in summer. On the plain below may be seen fields of grain and artificial gardens, and on the sides of the hills, exposed to the sun, are extensive vineyards.

Along the borders of the lake the fig tree grows in the open air, and experiments in the acclimatization of southern flora have succeeded admirably, proving better than any meteorological instrument the mildness of the climate. This is important for those coming in the spring time from a winter on the Riviera, desirous of taking the cure at Aix en route to Paris. It is a curious fact that the valley of Aix has never been subject to any sort of epidemic and is singularly free from endemic diseases. In the sixteenth century, the Senate removed from

Chambery to Aix to avoid an epidemic that was ravaging that part of the country.

Unusually large sewers were built to insure the tremendous outflow of water from the bathing establishment which keeps them constantly flushed, and is completed by bacterial purification by the Calmette process. In every respect the sanitation is exceptional. The streets of macadam are covered with odorless tar oil at regular intervals, and a force of street sweepers and water sprinklers are constantly in evidence; there is no dust and I must say it is uniformly the cleanest city I have ever seen.

Aix is on the great international railway line from Paris to Italy; and Calais-Brindisi, being nine hours' distant from Paris, with every modern comfort of traveling by *trains de luxe*. The town lies at the foot of Mt. Revard, which towers 4,305 feet above the summit of which can be reached by a funicular railway in one hour. I shall speak later of the relation of this mountain to the hot springs.

Aix is the greatest touring centre of the French Alps. It is served by excellent roads radiating in every direction, and is the pivot of sixty-four different excursions, all of them beautiful and captivating because of the beauty and grandeur of the scenery. It is sixty miles to Chamonix by the *Col des Aravis,* fifteen miles to Annecy and its beautiful lake, twenty-five miles to the celebrated convent of the Grande Chartreuse, and thirty miles to Grenoble.

At times it is useful to join a climatic cure to the Aix treatment, and it is admirably situated for this purpose. Across the lake, part way up the mountain of the *Dent du Chat,* is the Hotel *Col du Chat,* 1,400 feet above sea level, managed by a man from the Hotel Ritz, New York. Going up Mt. Revard, by the funicular railway, we come to Pughy Corbières, 2,000 feet, with a fine hotel; on the top of Mt. Revard, 4,000 feet, another.

Motor boats convey visitors on a tour of the Lake Bourget, the largest lake in France. The first point of interest is the Abbey of Hautecombe, one of the most beautiful church interiors I have ever seen, and as a monument, a unique and curious anomaly, for the building, dating from 1125, and the surrounding park, here in the middle of France, belong to the State of Italy, and were ceded by special treaty, for the reason that the church for centuries was the burial place of the House of Savoie, of which the reigning King of Italy is the head; and the delicate consideration of the French found a way to permit this property to remain under the dominion of the House of Savoie, and it is supported out of the privy purse of the King.

SPORTS AND AMUSEMENTS.

In the square facing the bathing establishment, there stands out conspicuously the Arch of Campanus, built in the third or fourth century. On the architrave can still be deciphered:

L. POMPEIVS CAMPANVS VIVVS FECIT.

A few hundred feet distant stands the Temple of Diana, built probably at the epoch of the Domitian Baths (122 B. C.). It is in a fine state of preservation and with additions made to it, forms the city museum, where are gathered many relics of great antiquity found in the neighborhood.

In the fifth century, the Vandals destroyed many of the most important of the Roman monuments, but upon entering the museum one sees the broken walls of the Temple of Diana, thirteen feet in thickness, formed of huge blocks of stone superposed, one above another, without mortar, and can readily comprehend why this massive monument was left standing.

Adjoining the temple is the chateau of the Marquis of Aix, built in the fifteenth century, and now occupied as the Town Hall.

At the right of the Thermal Establishment across the street is the Hotel Chabert, which is built over the old Domitian Baths.

At first this strikes one as being an example of vandalism, but upon consideration it nay not be a bad arrangement, for the remains of these ancient original baths can be visited in the basement, and the building covering them protects and preserves them from the elements. There are a number of brick columns in fine state of preservation, the bricks bearing the name of a well known manufacturer of the period, Clarianus.

There are two casinos, the Grand Cercle and the Villa des Fleurs. The first, one of the finest in Europe, with a magnificent interior housing, the opera, theatre, restaurant, dancing club and gaming rooms, library and writing rooms, and Punch and Judy Show.

The Villa des Fleurs, in a splendid park, has an open air theatre, café, dancing, restaurant and games. Saturday nights a fireworks display is given in the park.

The management provides a variety of entertainments during the season: Dog show, horse show, pigeon shooting, banquets, and on July 4th and 14th an annual procession of native costumes.

There are daily concerts and a celebrated orchestra gives classical concerts in the Casino theatre. In July the horse racing attracts the famous French stables in competition for the important purses and marks the height of the season. An annual regatta takes place on the lake for important prizes, and there is a yacht club, fishing club, and a fine park bordering the lake.

Six of the finest tennis courts in France are found here with a club house which is a favorite rendezvous for the younger set.

There is a commodious and attractive golf club, much frequented for afternoon tea. It is finely situated; has a course of nine holes, and there is a charming view of the surrounding mountains.

Aix possesses the most sumptuous hotels in the world, and it is frequented by the wealthiest and most aristocratic class of any thermal resort in France. There are also very moderate priced hotels and boarding houses.

Mr. Maurice Blake, an American college professor, has purchased and built a camp for boys on the border of the lake, named Camp Bourget, which is already a pronounced success.

MEDICAL.

The bathing establishment has been enlarged from time to time until, in size, it is the second largest in the world.

There are over two hundred employees, ninety of them being masseurs and masseuses, who are chosen from the men and women of the province, and the appointment is handed down from generation to generation. They have a universal reputation as the most expert in massage in existence.

The various departments of the establishment comprise twelve douche rooms with one attendant each (masseur or masseuse), thirty-four douche rooms with two attendants each; seven local douche rooms; four vapor bath rooms, with separate douche room; twelve vapor bath rooms with douche, known as bouillon; three hydrotherapeutic rooms with plunge bath and hot chamber; circular douches, spinal douches, shower baths, sitz baths with douche, six swimming baths; two very large for family use, an inhalation room where the hot sulphur water falls as rain into a central container filling the room with vapor in which the patient sits at ease; two rooms for spray treatment for nose and throat with twelve compartments each; two enteroclysis rooms (high enema); thirty-seven bathrooms of which nine communicate with douche rooms, permitting a bath before or after the douche massage; four submarine deep baths, where the patient sits in an armchair and is lowered into the plunge up to his neck; four baths fitted to give the vaginal douche; two rooms for foot baths in running water; a room for gargling treatment, and two fountains for drinking from the sulphur spring and the alum spring.

These two springs come from the Urgonian calcareous layers of Mt. Revard, by passages that are 160 yards apart. The temperature of the terrestrial layers rises one degree for every ninety feet.

Mt. Revard is 5,070 feet above the sea; these springs arising at the level of Aix have a constant temperature of 113° F. for one, and 115° F. for the other.

The characteristics of the waters are:

1. The presence of free sulphurated hydrogen, and the alkaline hyposulphites.
2. A preponderating quantity of calcium, magnesium, sodium, and aluminium sulphates.

The water is remarkable for whitish, flakey, threads called baregine, a fatty, unctuous, organic matter that acts like a soap, so the hands of the masseur pass easily without dragging or pulling and it is this element that renders the massage so wonderfully superior to all others.

Until 1857 the water issued from the mountain side in the rear of the establishment by seven streams. Italian engineers decided to unite these streams. First they took soundings, then made an excavation into the side of the mountain to an extent of 200 feet, when water burst forth, drowning two workmen and flooding the town.

This tunnel has been transformed into what is now known as the Grotto, and is open to visitors at fixed hours. One can see the great volume of water flowing in a cement conduit, and at the deepest end the great "pot holes" worn by the turbulent action of the water and which burst out upon the workmen as related.

The two hot springs flow in excess of 1,000,000 gallons per diem. A third cold spring that arises in the establishment flows an equal quantity and serves to cool down the douche to the temperature prescribed by the doctor, in each case.

In the park, in front of the establishment, are the kiosks of two cold springs: the Deux Reines and St. Simon. The first, of water similar to Evian, the other similar to Contrexeville. These waters are prescribed in cases where it is desired to create a diuresis or to flush the intestine, as adjunct to the baths.

The treatment at Aix is chiefly external: its application is shown in the following table:

PRIMARY INDICATIONS.

1. Chronic articular and atonic gout. Articular gout, after the acute attack has subsided. Socalled rheumatic gout, along with their neuralgic and muscular manifestations. Sciatica and lumbago.
2. Chronic rheumatism, monoarticular, or polyarticular, or muscular.
3. Sequelæ of acute, or subacute articular rheumatism, attached to infectious and pseudorheumatic (gonorrheal) arthritis, including certain forms of tuberculous rheumatism.
4. Joint affections of traumatic origin. The sequelæ of acute arthritis. Hydrarthrosis with stiffness, or commencing ankylosis. Periarthritis. Arthrosynovitis and tendinous synovitis, consequent upon dislocations, fractures and operations, complicated or not by trophic disturbances, edema and thickening.
5. Neuralgia of diathetic origin, or *a frigori;* Sciatica, cervicobrachial neuritis, professional cramp. Peripheral neuritis of alcoholic origin and otherwise.
6. Adjunct to the intensive mercurial treatment of syphilis.
7. Arteriosclerosis.

SECONDARY INDICATIONS.

1. Polyarthritis deformans in its early stage.
2. Sequela of hemiplegia, spinal paralysis.
3. Locomotor ataxia at a stage where specific treatment is indicated.
4. Sequelæ of phlebitis with hard edema and functional impotence of limb owing to stiffness of joint and muscles.

CONTRAINDICATIONS.

1. All forms of tuberculosis except the first stages of pulmonary.
2. Acute inflammatory disease of the joints.
3. Neuralgia accompanying organic disease.
4. Renal insufficiency in arteriosclerosis, arthritics with cardiorenal complications.
5. Gallstones.
6. Noncompensated cardiac disease.
7. Menorrhagia at the menopause.

The essential treatment at Aix is the douche massage practised under the continuous flow of hot sulphur water. It may be general, or local and supplemented by the steam vapor, needle spray, submerged bath, steam box bath, and swimming pools.

Dr. Daquin relates that the practice of massage was learned by the medical men with the army of Napoleon in Egypt, and brought to Aix by them; so it is only about a hundred years old.

Visitors coming to Aix for the treatment see almost immediately that it is much more detailed and important than the hydropathic treatment elsewhere.

The massage in combination with the unique composition of the waters, acts not only upon the skin, but also upon the subcutaneous tissues, the lymphatics and blood vessels. These factors working in combination produce a marked physiological result, which has been proven upon both healthy and affected subjects.

1. During the period of treatment the urine decreases in quantity and the total urates are so noticeably increased as to demand at times a diuretic water to facilitate the eliminative process.

2. The mineral and organic residuum is augmented and there is a progressive elevation of the coefficient, in relation of the total mineralization to the mineral residuum.

3. We find an increased nitrogen and sulphurous oxidation as shown by the rise in relation to nitrogen to urea, and in the acid sulphates to the total of sulphur.

4. We find a diminution of organic phosphorus, while there is only slight variation in the phosphates.

5. Increased elimination of uric acid.

6. In diabetic, gouty, phosphatic and rheumatic subjects we encounter a decrease in sugar and phosphates.

These interesting experiments in urinalysis show a profound modification in the nutritive processes, and make clear the pronounced action for good in rheumatic and gouty subjects.

The question often arises, is the Aix treatment admissible in arthritic subjects with cardiac complications.

Innumerable observations have demonstrated that the douche massage treatment lowers arterial tension with resultant alleviation of heart symptoms.

The douche massage promotes interstitial absorption in the tissues, which accelerates the movement of lymph in the vessels. It also increases the elimination of organic detritus and renders soluble the salts which form gouty deposits in the muscular and fibrous tissues.

Some patients criticize the treatment as producing nervous manifestation: this only happens when the patient foolishly tries to hasten the cure by taking the baths too frequently, or inducing the masseurs to give them a more energetic treatment. The treatment can be applied so as to secure a sedative or stimulating result; and this emphasizes the fact that the treatment should be followed only under the care and direction of one of the attending physicians.

The special influence of the Aix water is shown in an immediate and marked improvement, but shortly the patient complains of fatigue, heavy and sleepy feeling, with at times an increase in his pains; sometimes there are sensations of prickly heat and slight evidence of urticaria. These symptoms vary in patients, but are quite constant. The amelioration is sometimes constant from the outset, but most frequently toward the close of the treatment, and it is not unusual for the subject to find the maximum of benefit one, two or three months after.

Rheumatism is the condition that is most markedly benefitted at Aix, and experience proves that it requires several seasons of regular treatment to accomplish a cure; but there are instances of a complete cure in one season.

AUXILIARIES TO THE TREATMENT.

At a short distance, from the establishment is the Marlioz Spring, a cold sulphurous, alkaline, iodized, radioactive water. A completely equipped building is devoted to the treatment of eye, ear, nose and throat diseases. There are rooms for cold and hot spray applications, two large salons for dry inhalation of the products of the spring, gargling room, cold douche room and bathing rooms, with warm and cold douches. There are rooms set apart for those who desire private treatment.

These waters are specially indicated in lymphatic children and those of a scorbutic diathesis, and have produced good results in arthritic skin diseases.

The Zander Institute is worthy of special mention: it has the most completely equipped electrotherapeutical and mechanicotherapeutical installation in France.

BULLET WOUNDS AND THEIR CONSEQUENCES.

Dr. Manninger, a Budapest surgeon, read a paper at the medical union of Vienna on bullet wounds in relation to humanitarian warfare, in which he stated that in the recent war the Serbians and Italians used old style rifles, which were, however, excellent as regards the safety of the rifle carriers. Their bullets were of larger size and higher velocity than those of the Russians. Moreover, the Russian bullets were pointed, and penetrating wounds caused by them healed very well, whereas the Serbian, Austro-Hungarian, and Montenegrin bullets were very destructive of tissue. No tissues could withstand the impaction or in any way deviate the course of the Russian bullet; the wound is usually so cleanly incised that no pieces of clothing are carried in. The bone is rarely splintered, except in cases where shrapnel is used. The bloodvessels were very often injured, and Dr. Manninger reported several cases of aneurysm of the popliteal as well as of other arteries. Many of the nerve trunks were attacked. Although these wounds usually healed easily and without reaction, meddlesome examinations were sure to react unfavorably on the course of healing. Pus appeared only in those cases, where the tissues around the path of the bullet were invaded. Another complication arose from the frequently large cicatrices and tough adhesions. Out of 496 gunshot wounds there were twenty-seven cranial, twenty-one being through the substance of the brain. Deep penetrating lesions in this region were not accompanied by any destruction of the bones of the skull; the latter was observed only in superficial wounds. Six of the cases were accompanied by paralysis of the arm and leg; two presented the symptoms of cortical epilepsy evidently due to pressure and removed by operation. The general results of wounds of the lungs were rather favorable, all of them, with two exceptions, being penetrating. There was hemoptysis in twenty-two; subcutaneous emphysema in four, and extensive hemothorax in one, Dr. Manninger had observed forty-three cases of abdominal trauma, all of which were penetrating wounds; of these only five were fatal, chiefly owing to neglect of treatment; one death was caused by peritonitis. There were several penetrating wounds of the liver, spleen and kidneys.

Book Reviews

SYPHILIS.

Syphilis. By Burton Peter Thom, M.D. Illustrated with Sixty-nine Engravings. Philadelphia and New York: Lea and Febiger, 1922.

The author and publishers have combined to produce an interesting and easily readable volume on the subject of syphilis. It cannot be said that there is a crying demand for new volumes on this subject, and it must be admitted that much of the work of recent years has not been of much constructive value. As a rule, works on syphilis really are nothing more than compilations of the literature on the subject, the more pretentious volumes usually representing a deeper delving into the files.

While, therefore, the book under review is well written and printed, one is inclined to feel that it simply represents another book on a subject that has been almost done to death from a literary viewpoint. The book begins with the usual history of syphilis and continues along the usual lines to the end of the subject. The author has nothing new to offer, except several interesting chapters on the law, life insurance, and industrial efficiency in their relation to syphilis, and a brief chapter on how a syphilitic clinic should be managed.

The illustrations are excellent, the typography all that could be desired. On the whole, the author is to be commended for having crowded so much of what is known about syphilis within the covers of a volume of five hundred pages.

UROLOGY

Lehrbuch der Urologie mit Einschluss der männlichen Sexualerkrankungen. By Dr. Leopold Casper. Fourth Edition with 225 illustrations (some colored) and two colored plates. Berlin and Vienna: Urban and Schwarzenberg, 1923.

Casper has covered the entire subject of urology and male sexual diseases in this one volume of six hundred pages. Beginning with methods of examination, the author takes up the various portions of the genitourinary tract, and concludes with a thorough discussion of the functional disturbances of the sexual apparatus in the male.

The German approach to the subject of urology is maintained throughout the work, and to the German reading urologist or general practitioner, the volume will be found thorough, painstaking and concise in respect of detail and statement. In a work of such magnitude by so distinguished a surgeon, it is manifestly difficult and obviously useless to pick out what seems to be especially good or the contrary. Casper stands preeminent as Germany's leading urologist and his teachings may be accepted as representative of the thought of the day in his country on the subject of urology.

While we differ materially in many of these teachings, the difference is more often academic than real; nevertheless, it is well for the American urologist to know the German viewpoint and compare it with his own. In the main there will be found little opportunity for difference of opinion. Casper's latest work can be recommended unhesitatingly as a most valuable contribution to urologic literature by a master.

MICROBIOLOGICAL TECHNIC

Handbuch der mikrobiologischen Technik. By Dr. Rudolph Kraus and Dr. Paul Uhlenhuth. Band I, 2 Hälfte. Mit 83 Textabbildungen und 2 Tafeln. Berlin und Wien: Urban and Schwarzenberg, 1923.

The second half of volume I comprises nearly three hundred pages devoted to the preparation of media. In this there is nothing strikingly original. The formulæ are all copied from the original articles, and in general reasonable care has been given to the assignment of names, though it is obvious that where any question arises, the Teutonic, rather than the American, originator is mentioned. On the whole, there are a good many valuable technical methods that have come from this country concerning which no mention is made, for example, the special media for the differentiation of pneumococci so widely used in America are omitted. It is also strange to note that though Lister is stated to have used the dilution method for isolating organisms, the name of Pasteur is not mentioned in this connection. Except for such local peculiarities this volume forms a useful summary of the formulæ for most of the generally used culture media.

COLLECTED PAPERS

Collected Papers. From the Washington University School of Medicine. Volume I, 1921. St. Louis: C. V. Mosby Company, 1923.

The present volume of collected papers from the Washington University School of Medicine is the first of a series of annuals which are to be published under this title. The papers represent the work done in the Barnes and St. Louis Children's Hospitals, Dispensaries, and Laboratories of the School of Medicine and the Barnard Free Skin and Cancer Hospital covering many subjects and methods. An endeavor has been made to give the volume an interest which would be predominatingly clinical. Among the papers that have been reprinted are those of Wilson and Herrmann on Incomplete Bundle Branch Block, of Sachs on Brain Tumors, of Marriott on Nutrition in Infancy, of Shaffer on Antiketogenesis, of Opie on Tuberculosis Infection, and of Erlanger on Blood Volume and Its Regulation. Many other papers of value are to be found in this collection.

ARROW POISONS

Die Pfeilgifte. Nach eigenen Toxikologischen und Ethnologischen Untersuchungen. Von L. Lewin. Mit 75 Abbildungen im Text und einer Tafel. Leipzig: Verlag von Johann Ambrosius Barth, 1923.

This book contains the results of experimental investigations on arrow poisons stretching over a period of thirty years. It is a comprehensive work on toxicology and ethnology and includes a study of the poisoned weapons used by the aborigines of Europe, Asia, Africa, and America. The different poisons and weapons used by the various tribes are carefully described. The significance of this study lies in the facts that these poisons are still being used against both animals and man and that it has robbed the poisons of the mystery surrounding them; some of the poisons have even been utilized for therapeutic remedies. Such a work is of interest to the physician, the student of natural sciences, the ethnologist, psychologist, the student of the history of civilization and to every cultured person. The collection of this extensive material makes the future study of this subject easier. The symptomatic treatment of poisoning by arrow poisons is outlined.

PERSONALITY

George Gissing. An Appreciation. By May Yates. Manchester University Press. New York: Longmans, Green and Co., 1922.

George Gissing, the man, as he himself expressed himself. There is a danger in this sort of study of reading too much of the writer's character into his mouthpieces. A fascinating subject, however, to trace the notes of Gissing himself ringing through the network of many characters that he projected. And Miss Yates, we believe, has checked the romantic urge and stuck to authenticated facts. What we know from her we know for a certainty. The views Gissing held, his feelings, the all too few contacts of this thinker with the world of human friendliness are laid before us directly, simply. We can see more penetratingly into that complex personality; as far as can be, we know Gissing better for this sympathetic little work.

Medicoliterary Notes.

The Causation of Industrial Accidents is the title of an article by H. M. Vernon in the May number of the *Journal of Industrial Hygiene.* Another interesting article in the same number is Practical Mental Hygiene in Industry, by F. W. Dershimer.

* * *

The Devil's Disciple, by Bernard Shaw, which is being presented by the Theatre Guild, is a most entertaining play conceived by its author with truly Shavian psychology and philosophy. The company, too, is excellent, although perhaps Basil Sidney as the hero does the only outstanding piece of acting.

* * *

The United States Children's Bureau has recently issued as *Publication* 112 the results of an interesting and practical field study in Gary, Ind., of infant mortality.

* * *

Evolution and Religion, a small book by Henry Fairfield Osborn, replying to William Jennings Bryan's socalled fundamentalist views, has recently been brought out by Scribner's Sons.

* * *

The issue for June 1st of *Public Health Reports* contains a full index of the State tuberculosis laws, compiled by James A. Tobey, of the National Health Council, Washington, D. C.

* * *

The Advisory Committee on Health Education of the National Child Health Council has recently issued as the first number of its series, *School Health Studies,* a report entitled *Health for School Children.* The study is published by the United States Bureau of Education.

* * *

The story of the latest scientific expedition, headed by the naturalist, William Beebe, in the steam yacht *Noma,* to the Galapagos Islands off the west coast of South America, will be told by Mr. Beebe in book form. The title of the work will be *Galapagos—World's End,* and it has been announced for publication in the autumn by Putnams.

* * *

Frank R. Stockton's *The Casting Away of Mrs. Lecks and Mrs. Aleshine* has been a steady seller ever since it was first published by the Century Company in 1886. The present illustrated edition was first issued in 1892, and it was recently reprinted for the tenth time. Over a thousand copies were sold last year. This was the first novel ever published by the Century Company.—*New York Times.*

* * *

The *Journal of Social Hygiene* for May contains an article by J. S. Lawrence on the New York State venereal control program.

* * *

The Plymouth Congregational Church of Seattle, Wash., has opened a medical and psychological clinic in cooperation with some of the physicians of the city and the staff in psychology of the University of Washington. The clinic will in no way resemble, it is announced, the late Emmanual Movement of Boston, for the clergy will have nothing to do with the treating of the patients.

* * *

The recently published annual report of the New Jersey State Hospital at Morris Plains announces that the new psychiatric reception building for four hundred patients has been constructed and will be ready for occupancy as soon as the equipment has been installed.

* * *

Among June publications which should be of interest to the psychiatrist are the *Psychology of Laughter,* by J. Y. T. Greig, which will be issued by Dodd, Mead & Co., and the *Story of the Development of a Youth,* an autobiographical study, by Ernst Haeckel. Two publications announced for the fall by Brentano's promise to be fields for personality study of abnormal types—a translation of Marcel Proust's *Les Don Juanes,* which is a psychological study of the female Lothario, and Rafael Sabatini's *Life of Cesare Borgia.*

* * *

The present Status of Sanitary Engineering is the title of an informative article by Harrison P. Eddy, in *Public Health Reports* for April 20. Mr. Eddy's discussion includes modern methods of water supply and purification, of sewerage, drainage, and the disposal of waste, refuse collection and disposal, eradification of the mosquito and infection carrying vermin, and air supply and purification.

The New York State Department of Health has published a very full special report on mortality from influenza in the State during the great epidemic of 1918-19. The author of the report is Dr. Otto R. Eichel, director of the division of vital statistics.

Practical Therapeutics

THE USE OF DYES IN ULCERATIVE COLITIS

By Anthony Bassler, M. D.,

New York.

The term ulcerative colitis is employed to describe a group of conditions in which persistent diarrhea of fluid feces with the passage of blood, pus and mucus have been existent for a considerable length of time. With this, ulceration in the sigmoid and upper rectum and evidence of congestion and inflammation must be observed, a high pyogenic bacterial content in the gut proved, a reduction of general health, and subjective symptoms of irritability of the colon. In these conditions syphilis, tuberculosis, and parasitic infections, etiological neurological factors, dietetic indiscretions, conditions in which the colon has a friable mucosa, and simple nonulcerative biological errors are all excluded. The type of cases I am speaking of may be best designated as infectious colitis with ulceration, but the old term ulcerative colitis is more generally accepted.

For a status of illness that is common enough, and has been for centuries, this trying disorder is too little understood and is rarely treated except by rest in bed, a milk or bland diet, fractional doses of castor oil, salol and opium, bismuth, colonic irrigations, and surgery. The severe and difficult cases comprise those in which simple methods of treatment have been employed, or no treatment at all, and perhaps those in which the patients have not got well in spite of the methods employed. Analysis of these conditions shows that the majority of these infections disappear in a relatively short period of time. In a small percentage of cases, however, the infection persists and finally becomes mucosal, remaining as a mixed infection not always easy or possible to define in specific or symbiotic ways. In cases in which the condition has been standing for at least one year without abatement of symptoms which have been studied and treated, some rather worthwhile results have been accomplished through the use of various dyes. Unfortunately there is so much variation in biological ways and even in identical infections with the same dye that it is difficult to present a definite narration of experience. Rather than to complicate it with confusing conditions, I shall offer a simple classification for the finding of etiological causes easily carried out in any laboratory as a guide in the selection of dye that has most often answered.

In a case representing the symptomatology mentioned, a stool specimen is gram stained in a differential way and the gram positive and negative organisms counted as one would leucocytes. One third gram positive and two thirds gram negative are taken as the standard of normal and departures one way or the other from this may classify the case for dye selection. This simple classification answers in perhaps eighty per cent. of the cases, a large enough percentage to be practical for the average worker.

All of the ordinary pyogenic streptococci and staphylococci are gram positive, this being one of their laboratory characteristics for identification. The organisms of the coli-dysentery-typhoid group are all gram negative and among these the semiparasitic Bacillus coli is most often met with. The organisms mentioned are the factors in about four cases out of five and if one can work intelligently with them, the dyes can serve a useful purpose. The smaller percentage of infections, which usually are mixed, require careful laboratory study and agglutinizing reactions for significant identification, and not wishing to confuse a picture that anyone could carry away and a simple procedure that anyone can carry out, they are not incorporated in this article.

MERCUROCHROME 220.

This has been used in the gastrointestinal tract. The compound contains from twenty-three to twenty-four per cent. of mercury in organic combination with the dye molecule. In this form the mercury, while retaining most of its germicidal value, does not show the chemical reactions of the mercury salts, that is, is not precipitated by alkali or ammonium sulphide, nor does it precipitate protein, and because of this fact concentrated solutions are supposed to be harmless. It must thus be plain that this substance does not depend upon its dye for bactericidal effect but upon the mercury content instead. From this viewpoint it differs from the dyes proper but is mentioned here because it is considered by many primarily as a dye, and its action is said to be due to the dye substance wholly or in part, whereas the fact is that the dye factor is simply one of making the mercury less irritating and making it possible to employ it in large doses without seriously affecting the body tissues.

Einhorn (1) has reported two successful cases in which with one half of one per cent. calcium carbonate solution, the employment of the intestinal tube and one per cent. mercurochrome solutions were employed. The gratifying results obtained are rather confused because one half of one per cent. calcium carbonate solutions, as well as the mercurochrome, are distinctly bactericidal and regular transintestinal lavages alone will benefit many cases whatever the solution employed. There is probably also some benefit in the use of the intestinal tube because the tip could deliver the solution into the ileum and from it quickly into the colon—the usual site of the ulcerative area.

Mercurochrome solution was employed in three cases of syphilitic colitis with ulceration with benefit, and in a number of bacterial types also with benefit. We have found that in the intestine this substance is far from nonirritating. We do not know why, but intolerance to its use and even the quick precipitation of a marked acute colitis was far too common for its employment. We have carried the percentage of the solution down from five to one and yet had severe results. In the last year we have used it by enemata and still had unhappy results. It is probable that the small amount of the solution which Einhorn employed (two ounces of a one per cent. solution) would be tolerated, but relying on this substance alone in large enough quantities to influence the bacteriology it too often is followed by a discharge of almost pure blood, marked abdominal distress, fever, and intense irritability of the colon that lasts from one to two weeks from one injection. We feel that this is due largely to reaction of the intestine to the mercury content and we have practically discontinued its use and are now employing the straight dyes, which, by the way, may prove irritating enough to give one unhappy moments.

Animal experiments and their use in humans in many ways show that neutral acriflavine and gentian violet are certainly most innocuous. In solutions of moderate strength even the sensitive conjunctiva will not become irritated by them. Yet every now and then their employment in the intestine will light up abdominal distress, with acute distention of the abdomen from gas, griping pains, and other conditions. At first we believed this to be due to some chemical effect of the dyes on the tissues, but further observation and study of cases in large enough classified groups suggest that this is not the case. It is more probably due to an effect of the dye on certain restraining organisms present in the gut at the time of the instillation of the solution. The organisms of the Bacillus coli group are largely protective. If in a given case, in which acriflavine is employed, they are acting as such against an inimical bacteriology that would not be influenced by acriflavine, infecting anaerobes are suddenly given full sway with the production of alarming although not fatal clinical symptoms. Conversely, if the infecting organisms are of the gram negative type, the use of gentian violet may bring about lesser degrees of distress by restraining the gram positive anaerobes, but these are far easier of tolerance and control. When possible, it is therefore important to determine which organisms are present before either of these dyes is employed. But when this is not possible, the results obtained by the use of one of these dyes, with the symptoms that follow, will often give one the important information required as to which dye to employ in a routine way.

ACRIFLAVINE (NEUTRAL).

Browning, of Glasgow, proved that this substance in serum has bactericidal power twenty times as great as bichloride of mercury and eight hundred times as powerful as phenol or dichloramine-T. In the presence of serum, acriflavine was the most potent bactericide for both staphylococcus and Bacillus coli and equally so for the enterococcus and the anaerobe Bacillus œdematis maligni. These are potent organisms for mischief in some of the cases. So far as the intestine is concerned, in a general way it answers best for those infecting organisms that belong to the gram negative class. Among these may be mentioned: Bacillus dysentericus, Shiga, Kruse, Bacillus coli (semiparasitic types), Bacillus pyocyaneus, Bacillus alkaligenes, Bacillus paracoli, Bacillus paratyphosus, Bacillus typhosus, Bacillus enteritidis, and Bacillus œdematis maligni (gram positive).

This dye may be employed with comparative safety in the intestine in strengths of from one in one thousand to one in five thousand solutions and in quantities up to one litre. It may be employed by duodenal tube, preferably in normal saline solutions, to approximate the serum as nearly as possible, or by enemata. Used in 0.1 gm. enteric coated tablets taken frequently during the day it is of benefit at the conclusion of active treatment.

GENTIAN VIOLET.

To Churchman (2) credit is due for attention being drawn to the bactericidal effects of this dye. In the main our investigations agree with what he has presented. It has been shown, with some modifications that are not of cardinal importance, that gram positive organisms are destroyed by the dye while those of the gram negative group are comparatively undisturbed. Some resisting and hardy spore bearing gram positive bacteria are astonishingly sensitive—and may represent an important inimical content in an individual case. Unfortunately, the growth of the most common offender, the Bacillus welchii, may be hindered but never stopped. This is also the case with the Bacillus sporogenes, an organism of some importance in this connection. Observation shows that the designation of gram positive or gram negative indicates a fundamental characteristic of bacteria but that there are some exceptions in different affinities to gentian violet in different strains of the same bacteria. On the whole, however, the behavior of the bacteria with this dye is constant and clear cut enough to be regarded as a biological characteristic of constancy. The gram positive organisms in the intestinal tract that are inhibited by gentian violet and which may be factors in infectious colitis are the following: Streptococci, staphylococci, Bacillus anthracis, Bacillus putrificus, and Bacillus welchii.

Gentian violet is safe to employ in strengths of from one in one thousand to one in eight thousand solutions and any quantities. It is used by duodenal tube in any type of solutions and best in hypertonic ones. By enemata or in enteric coated pill, 0.5 gm., it can be used frequently without harm.

The observations on the effects of dyes are not clinical but those of laboratory procedure. Considering the variability of the same strains of bacteria in a biological sense and also the differences existing them all, especially the groupings one sees in intestinal canals, we not only have difficulty in determining whether they are causative factors, their importance in diagnosis and their reaction to dyes, but we have the great problem of a rapid change in the chemistry of the dyes when thrown into the long intestinal canal, where any bactericidal power they may have is quickly vitiated. By immediate contact all dyes produce prompt and fairly deep staining of visible mucous membranes. This occurs in the gastrointestinal tract when introduced into the rectum and it takes about fourteen hours for the color to disappear. If the dye comes in contact with a length of mucosa, various body fluids, fecal substances, etc., while still in solution, it undergoes a rapid oxidation or reduction, thus its indirect employment by duodenal tube instead of directly by the anus makes a difference in mucosal staining and sometimes in the clinical results. If the intestinal canal were a closed cavity like an empyema sac or an infected joint better staining of tissue and bactericidal effect of the dye would be obtained.

In testing the dyes we have employed a bland diet in the severe cases for a short time, but ample and full meals in most cases all the way through. The dietetic restrictions were characterized by no interest and a forcing of food in the majority of the cases. Bismuth, opium, or other drugs were not employed and the adjuvant of rest was not utilized. No abdominal applications were permitted, and no irrigating solutions of any kind other than the dye solutions were employed. In a word, the bacterial diagnosis being made, we depended entirely upon the bactericidal effects of the dyes in changing the biology in the gut. Altogether thirty-seven cases of infective and ulcerative colitis were treated and studied during acriflavine or gentian violet solutions until now we feel that sufficient information has been gained to permit of more rounded procedures and a wider routine in the clinical handling of them. These may be expressed in the following conclusions:

CONCLUSIONS.

In all chronic diarrheal conditions, syphilis, tuberculosis, and the parasitic conditions must be carefully excluded from the bacterial cases.

It is in the latter cases that the most intractable infections and ulcerative states are encountered and these cases should have the advantage of a bacterial diagnosis when this is possible.

The gram differential staining method is valuable to a considerable extent in judging the type of biology present and suggesting the dye selection. In doubtful cases subculturizations and study of individual bacteria may be called for.

Most of the pyogenic organisms are gram positive and gentian violet is indicated, and on the other hand the bacteria of the typhoid dysentery coli group are gram negative and best influenced by neutral acriflavine. Mercurochrome 220 is potent in all because of its mercury content, but it is very irritating. It is especially indicated in the syphilitic cases.

These cases represent all grades of intractability to treatment. Some are so simple that diet and medication answer, in others lavage of the intestine with a saline, hypertonic, chlorine or similar solution answer the purpose. In the more severe cases, gentian violet and neutral acriflavine solutions are potent for good in influencing an abnormal bacteriology and are well worth a trial.

In but one of the thirty-seven cases in which dyes were used was a fistulous opening in the right colon required. In eleven patients who had fistulous openings when they came under observation, the openings were closed before treatments were begun with the dye solutions.

The dye to be used in a given case having been selected, the best procedure is to irrigate the intestine with a hypertonic solution containing sodium or magnesium sulphate and phenolphthalein, using up to 1,000 c. c. When the bowels are flushed and active purgation is taking place, though the duodenal tube is still *in situ*, the dye solution is run in. The hypertonic salt solution cleans out the canal and has it in active peristalsis when the dye solution is instilled, and in this way it is not changed so much in rushing through the intestine and has immediate contact with the mucosa which is infected. With the acriflavine this method is essential, whereas with gentian violet the dye may be added to the hypertonic solution.

The dyes may be used by the patient at home by enemata and in pill or tablet form. This enhances the result.

Dieting may be of some value but with the dye therapy it is not important. Rest is a valuable adjuvant, and symptoms of distress may have to be controlled by medication.

By this method of treatment, even in seriously septic cases with fever, surgical operations seem to be no longer necessary and only in exceptional cases need to be used.

After clearing out the infection and repairing the ulceration, these colons remain friable, and for such occasional doses of bismuth, building up the body, and the use of agaragar by mouth are of value. Finally, as was proved in a sufficient number of nonulcerative conditions, the two dyes, neutral acriflavine and gentian violet, have potent powers in influencing intestinal bacteria.

Drugs in the Treatment of Diabetes Mellitus.—P. J. Cammidge, J. A. Cairns, Forsyth, and H. A. Howard (*Lancet*, December 23, 1922) state that it is unlikely that treatment by drugs will ever replace control of the diet in diabetes and that lack of care in working out an appropriate diet can be compensated by the administration of drugs. They attempt to show that if the food tolerance has been accurately determined and is found to be inadequate, then, and only then, may the aid of appropriate drugs be invoked to enable a maintenance diet to be taken and prolong the patient's existence under more comfortable conditions; also to record their experiments, indicating the way in which various drugs control carbohydrate metabolism, thus laying the foundations of a rational therapy. In diabetes, accurate diagnosis is the only sure basis of treatment, and they believe that the pancreatic, hepatic, and other types they have described should be differentiated by analyses of the blood, urine and feces before serious treatment is commenced.

Quinidine in Auricular Disease, Paroxysmal and Established.—John Parkinson and J. W. McK. Nicholl (*Lancet*, December 16, 1922) state that quinidine is indicated in paroxysmal auricular fibrillation because it either inhibits the attacks or reduces their incidence in some cases, which no other drug, not even digitalis, will do. It has little or no effect in paroxysmal tachycardia. It is likely to prove valuable in auricular flutter because it sometimes restores normal rhythm immediately, and if not, it may succeed after digitalis alone has converted the flutter to fibrillation but not to normal rhythm. In a small proportion of cases with established auricular fibrillation, quinidine restores normal rhythm, which continues indefinitely with great clinical benefit. In most cases quinidine is unsuccessful in that normal rhythm is not restored, or when restored is not maintained, or restoration is unattended by clinical improvement. After explaining its limitations to the patient, a trial of quinidine should be made in chosen cases of auricular fibrillation where there is no history of embolism, no great enlargement and no serious failure.

Abstracts from Current Literature

PEDIATRICS.

Summer Diarrhea in Infancy.—Wilfred J. Pearson (*Practitioner*, July, 1922) says that in treatment we are faced first with the problem of managing the acute stage. The main indications are to eliminate toxins by stopping all food; to evacuate the stomach and bowels; to combat collapse by restorative measures; to replace fluid loss, and to neutralize toxins by giving alkalies. In the later stage the chief concern will be to find a suitable diet.

Evacuation of the stomach and bowel may be effected by washing out the stomach with sodium bicarbonate solution, one dram to a pint of water, and irrigating the colon with warm water or saline, by giving a dram or two of castor oil, or small doses of calomel every hour for six doses followed by milk of magnesia. In severe cases, when diarrhea is profuse, purgation must be avoided. If a child is much collapsed a mustard bath, a tablespoonful of mustard to a gallon of water at a temperature of 100° to 105° F., is a valuable stimulant. If it reddens the skin a good prognostic sign is furnished. Then the child should be put to bed in a warm, well ventilated room. If further stimulation is needed five to ten minims of brandy well diluted may be given every hour or two. If necessary, subcutaneous injections of strychnine, or of camphor in olive oil (gr. ¼ in five minims), may be given. To replace excessive fluid loss subcutaneous injections of normal saline are indicated, three to six ounces at a time, at intervals of five or six hours, at a temperature of 105° F. In very urgent cases saline may be given intravenously.

In the breast fed a temporary withdrawal from the breast is advisable in most cases, water being given for twelve to twenty-four hours. When feeding is started again, skimmed maternal milk should be given; later, when a return is made to breast feeding, only short feedings should be allowed at first, the time being gradually extended until full feedings are taken. Plenty of water must be given throughout, especially when the child is being underfed. In the artificially fed all food must be stopped for from twelve to twenty-four or forty-eight hours, until the acute symptoms subside, boiled water, weak tea, or rice water only being given. This is essential. The return to food is difficult and no definite rules can be laid down, but each case must be treated on its merits. Whatever kind of food is chosen attention must be given to the following points: to give small amounts at first; to make additions slowly; to note the effect of such increases on the temperature, the stools, and the general condition. Generally speaking, it is best to avoid milk until the temperature is nearly normal. In all cases fat should be left out at first. This leaves the option of a diet mainly protein or mainly carbohydrate. If, in a case in which the stools are strongly acid, starvation causes a decided improvement and a fall in temperature, a protein diet is indicated. Boiled skimmed milk may be added cautiously to rice water, giving at first one quarter to one half an ounce every second feeding and gradually increasing if improvement is maintained. The next step, the stools now being formed, is to add sugar cautiously in small amounts to equal parts of skimmed milk and water. Buttermilk is often successful as an alternative, or a half cream dried milk, or ordinary milk and water. Whey is often well tolerated, but in many cases is not satisfactory. In other cases the persistence of the temperature and the continued frequency of the stools suggest an infective process, and then it is often better to give foods containing a little residue. If skimmed or peptonized milk does not agree, greater success is often obtained with a malted food or a malted milk.

In a child over six months old who presents definite signs of colitis, the best treatment is to give arrowroot water, one to two tablespoonfuls to the pint, or Benger's food at first and to add skimmed milk or buttermilk without fat later and by degrees.

Drugs play a relatively small part in the treatment. After the intial stages, when the diarrhea persists, small doses of castor oil may be valuable. Large doses of bismuth may be of much value when the large bowel is affected. Opium is useful when the stools are very frequent or there is severe pain; it is of the greatest service in the choleraic type. Generally speaking, it should not be prescribed early, until the bowel is emptied, if cerebral symptoms are definite, or if motions are small and offensive.

Constipation in Infancy and Childhood.—Eric Pritchard (*Practitioner*, July, 1922) says that as a factor both in the causation and treatment of constipation diet is undoubtedly important, but not so important as regularity of habit and suitable training, and that when babies are trained to have only two actions a day "at call," the motions are usually butterlike and formed. The management of constipation differs in breast fed infants, in bottle fed infants, and in older children.

When constipation is due to some fault in the food of a breast fed infant, it is difficult to make a correct diagnosis. The fault may be one of quantity or of quality. If of quantity, this may be proved by estimating the total amount of milk consumed in the twenty-four hours by the application of the "test feed." If of quality, the error may sometimes be detected by an analysis, but not as a rule. After such errors in quantity and quality as can be detected have been corrected, the educational régime may be reinforced by a small daily dose of the following mixture:

Tinctura aloes	♏iij
Tinctura belladonnæ Tinctura nucis vomicæ } aa	♏j
Syrupus sennæ	ʒss
Syrupus ficorum, ad	ʒj

The dose to be gradually reduced till not needed.

In bottle fed infants modifications in the food are indicated. It is necessary to consider whether the condition is due to deprivation of such accessory elements as organic salts, vitamines, lecithin bodies, or extractives, which would predispose to rickets and atony of the bowel. The routine treatment by increasing the cream, or adding olive or cod liver oil, is unsound, as is also the giving of certain proprietary foods, which consist mainly of carbohydrates. A regular practice of giving three or four ounces of vegetable or bone broth is advised. For the older children reliance must be placed chiefly on the observance of the cardinal rules of physiological feeding. It is generally due to defective training in infancy and to the abuse of drugs. Purges, enemata, and suppositories are harmful. Physical exercises, designed to bring the abdominal muscles into play, are helpful.

Tuberculous Bacillemia in Infancy.—Henri Catherine Chisholm (*Lancet,* September 2, 1922) March 14, 1923) report that the only point of interest from an intensive study is that bacillemia is a little less frequent in the nursing than in the adult. Under six months of age the prognosis in tuberculosis is extremely grave, but after the sixth month the prognosis improves and approaches that of adult life.

Malnutrition, or the Infantile Dystrophies.—Catherine Chisholm (*Lancet*), September 2, 1922) asserts that in the treatment of malnutrition, a careful history and study of the child are essential. The debilitated atrophic type of child requires stimulation of the appetite and metabolism by massage, electricity, baths, stimulants, nursing and general hygienic measures; the body should be kept warm, the food should be well balanced and increased as rapidly as possible and the signs of intoxication, acidosis, febrile temperature and infectious diseases must be guarded against. In intestinal disturbances, sickness, or vomiting, the diet should be light and increased cautiously; the offending element of the diet should be sought and eliminated. The tolerance for fat is regained with difficulty, but sugar tolerance is regained fairly easily by utilizing the various forms of sugar and starch; protein is well tolerated, especially if the curd is lightly and easily passed through the stomach. The diet should be built up slowly and with great care until one that is properly balanced has been obtained.

Treatment of Infantile Paralysis in Children.—G. R. Girdlestone (*British Medical Journal,* September 30, 1922) proposes the following plan of treatment for infantile paralysis: In the first stage, the child is completely and comfortably wrapped in cotton wool or gamgee tissue and placed on a Thomas double spinal frame with a headpiece, on a soft saddle, with the feet at right angles on footpieces and the pelvis true. If the arms are affected they are held abducted, with the elbows flexed. This immobilization is maintained for at least six weeks, or longer if necessary. After all tenderness has disappeared, light massage without movement is begun. In the second stage, the requisities are: 1, posturization of the trunk and limbs; 2, correction of any deformities that may have developed, and 3, the resumption of function by, a, stimulation of the skin by light massage, b, reeducation and comencement of active movements, and c, locomotion without overstrain. In the third stage, the patient's capabilities are developed, either by stabilization of the joint, transplantation of tendons, etc., or suitable appliances; operations, such as arthrodesis, are postponed until after the age of eight or ten and patients with flail knees are kept walking in calipers until after the school life is completed.

Infantile Eczema.—Howard Spohn (*Canadian Medical Association Journal,* July, 1922) considers this disease to be due to a congenital metabolic defect, and fat intolerance to be the most frequent cause. In all severe cases protein skin tests should be made. The child should be put on evaporated milk or boiled skim milk, starch should be substituted for sugar, and all raw fruit or fruit juice should be eliminated from its diet. Usually they can be given enough fat soluble vitamine in codliver oil to protect against rickets. After the severe symptoms have subsided some patients can be given orange juice. Local treatment consists of using olive oil in place of water for cleansing, and the application of tar and resorcin ointments. No benefit can be obtained from this without the very active cooperation of the nurse or mother. The child must be kept from scratching, the arms being put in restrainers and the hands in mitts, the legs kept apart, if affected, so they cannot be rubbed together. After the scales and crusts have been removed with oil a thirty to fifty per cent. tar ointment with one per cent. salicylic acid may be used, but sometimes this is too irritating and more applications are advisable. For the scalp a four per cent. resorcin ointment is usually effectual. After the severe symptoms are over any bland oily substance will suffice.

Sleeplessness in Infants.—Charles E Sundell (*Practitioner,* July, 1922) says that it is well to bear in mind that the cause for a baby's wakefulness is most often a simple one, and simple causes should be sought for first. Attention to the temperature of the cot and of the room, screening of lights, and the avoidance of clatter or loud conversation, are so obvious as to require nothing more than mention. Most common of all are the discomforts of the gastrointestinal system—flatulence, colic, hunger and, what is so apt to be overlooked, thirst; many a child cries in the night for fluid, and is given instead the makings of a lump of casein curd. It is always worth while giving a wakeful child a drink of water; it is seldom refused, and often satisfies.

Two other causes of wakefulness must be borne in mind—irregular habits and excitement while awake. The temptation to postpone the time for a baby's sleep, so that he may be admired by some relative or friend who is late in arriving, or so that his nurse may finish some work on which she may be engaged, must be strongly resisted. A sleepy child who is kept awake exhausts his nervous energy very quickly in peevish restlessness, and when preparations are at last made for his sleep he may be too weary to settle down. Physiological proof of this indisposition for slumber is to be found in the increased reflex irritability of a sleepy child, an irritability which is soon soothed into sluggishness should sleep be not too long delayed, but which persists and increases if the balm of sleep is withheld.

Regularity of habits is one of the sheet anchors by which the barque of an infant's health is secured. The reestablishment of a regular routine, after even a short break, frequently calls for patient perseverance on the part of the nurse, but though the child may protest vigorously for several nights, absolute firmness seldom fails to procure the desired result.

Compulsory Exclusive Feeding With Butter Flour Soup During the First Two Weeks of Life.—Johannes Schoedel (*Monatsschrift für Kinderheilkunde,* July, 1922) reports good results with the feeding of a butter flour mixture in fifteen infants who had to be fed with this mixture after two to thirteen days' feeding with breast milk. The feeding was begun with small amounts and was gradually increased until a total of 150 grams to the kilogram of body weight was given at the middle or end of the second week; this amount was administered as long as the weight continued to increase. When the increase in weight ceased, the amount of the feeding was gradually increased to 160, 170, or at the most 180 grams to the kilogram of weight. The mixture was prepared in the manner originally advised by Czerny and Kleinschmidt. Another guiding principle was to give one-third butter flour mixture if the weight was below 3000 grams and two fifths butter flour mixture with a weight above 3000 grams.

Colon Bacillus Agglutinins in Infants with Disturbed Nutrition.—E. Aschenheim and D. Holstein (*Monatsschrift für Kinderheilkunde,* July, 1922) report that in three cases out of twelve, they found an unusually marked agglutination in the blood serum of infants with disturbed nutrition, which led them to believe that the agglutination was the result of the disease process. One case showed a typical intoxication, with sugar and albumin in the urine, convulsions, toxic respiration, profuse diarrheas and the vomiting of hematin. Another case showed an acute milk albumin dyspepsia in a child affected with syphilis. The most marked agglutination occurred in the third case, an infant eight months old, with dyspepsia and colon bacillus cystitis. These findings gave support to the theory that a specific reaction was present in these three cases. In both of the cases of socalled dysentery, the agglutination was negative toward the excitants of the dysentery but was positive toward the colon bacillus.

The Ascent of Colon Bacilli in the Nutritional Disturbances of Infants.—Eugen Kramár (*Monatsschrift für Kinderheilkunde,* July, 1922) reports on the clinical and bacteriological investigations in parenteral infections and chronic fermentative dyspepsias. In the former there is a parallelism between the occurrence of the dyspepsia and the invasion of the duodenum by the colon bacilli. There are also dyspeptic disturbances, in which the invasion of the duodenum by colon bacilli is absent and, on the other hand, there may occasionally be colon bacilli in the duodenum without any diarrhea and therefore the dyspepsia is not attributable to the ascent of the colon bacilli. No increase in the agglutination titre, worthy of mention, toward the strains of colon bacilli was demonstrable during the course of the parenteral dyspepsias. On the other hand, some of the cases of chronic fermentative dyspepsia regularly and consistently showed invasion of the duodenum by colon bacilli and a fairly high agglutination titre was demonstrable in the patients' blood serum toward their own strains of colon bacilli, particularly toward the strains cultivated from the duodenum or the stomach. The bacteria appear in the stomach only occasionally in acute exacerbations.

The Blood Platelets in Infancy.—Klaus Keilmann (*Monatsschrift für Kinderheilkunde,* July, 1922) states that with the Spitz method the thrombocyte values vary between 48,000 and 192,000 to the c. mm. of blood. Values below the minimum of 40,000 and those above 200,000 to the c. mm. should be considered as pathological. The number of thrombocytes is not influenced by the time of the day nor the taking of food. In premature infants, no diminution in the number of thrombocytes was demonstrable. In dystrophic children, the maximum values do not seem to be as high as in normal children, but the minimal values seem to correspond with those found in normal infants. In one case of infantile sepsis, an extremely low number of platelets (24,000) was found, associated with a positive Rumpel-Leede sign; with the subsidence of the acute symptoms the number of blood platelets was increased to normal.

The Effect of Position in the Family on the Health of the Child.—R. H. Vercoe (*Lancet,* October 7, 1922) found that in intelligence, height, weight and pigmentation there is no appreciable difference between any of the children in a family; whereas, in the incidence of disease, the worst child is definitely the eldest, while the best is definitely the eighth child and upwards. The author, therefore, draws the following conclusions: 1, that the quality of the average child does not deteriorate in any way with successive pregnancies; 2, that the quality of the family does not deteriorate in any way with increase of quantity, inasmuch as the eighth children, who are drawn entirely from large families, are inferior to none and superior to the eldest, who are drawn largely from small families.

Instillation Treatment of Enuresis in Childhood.—William R. Barron (*Southern Medicine and Surgery,* June, 1922) describes his method of treating enuresis in children by installations. In girls he uses a small glass female catheter with a rubber tube attached. With aseptic precautions the catheter is introduced into the bladder and through it is instilled one ounce of a three per cent. argyrol solution. This is allowed to remain in the bladder for from thirty minutes to one hour, when it is voided. This is done daily or every other day, and the strength of the solution is increased until in some cases a ten per cent. solution can be borne. In boy patients the argyrol solution was injected into the urethra with a bulb syringe, forcing it into the bladder. Barron has treated about thirty-five cases, mostly of boys, at least seventy-five per cent. of whom have remained cured, some of them having had as few as three treatments.

The Influence of the Hydrogen Ion Concentration and Buffer Value of Foods on Digestion, With Special Reference to Infancy.—Harold K. Faber and Fannie Hadden (*Medical Clinics of North America,* September, 1922) conclude: 1. Optimum conditions for the action of the digestive enzymes demand that certain grades of acidity be established in the stomach and of alkalinity in the intestine; the ease of digestion of any food depends upon the ease with which it permits the requisite reactions to be established in the gastrointestinal tract. 2. The reaction and buffer properties of colostrum indicate that it is intended for intestinal digestion. The development of gastric digestion is gradual and probably not completed for a considerable period of time under normal conditions. 3. The reaction and buffer properties of protein milk and lactic acid milk suggest that their curative effect may be due to stimulation of the gastric function to take up a greater share of digestion. 4. Most of the carbohydrate infant foods have little or no buffer value and hence do not materially affect the digestibility of milk, but the foods containing potassium carbonate are somewhat alkaline and interfere to some extent with gastric digestion.

Child Welfare.—Robert Bell (*Medical Times*, London, June, 1922) looks upon a superabundance of starchy food, such as white bread, corn flour, arrowroot, and decorticated rice, as pernicious to child welfare. On the other hand, whole wheat bread, oatmeal, and barleymeal are highly nutritious. Fresh milk in its unaltered condition and uncooked fruits are of great dietetic value. Vegetables should be cooked without water in a double boiler to conserve their natural salts. Dried fruits, such as dates, figs, and sultana raisins, are highly nutritious and much favored by children. A number of children, mostly boys, with tuberculous glands and bone tuberculosis, regained their health under a diet which excluded starchy foods, such as white bread and potatoes, and which consisted of whole wheat bread, oatmeal porridge, milk, cheese, eggs, fruits, and salads. To this regimen was added four or five grains of calcium chloride three times daily after meals.

RESPIRATORY DISEASES.

Seasonal Variations of the Weight of Tuberculosis Patients. — N. J. Strandgaard (*Acta Medica Scandinavica*, November 29, 1922) estimates that the average weekly gain in weight at the Danish tuberculosis sanatoriums calculated for a period of ten to twenty years is between 200 and 250 grams for each patient. The gain in weight varies considerably from week to week, it may be two to three times higher or lower than the average, consequently also negative, the latter occurring five to six times a year, sometimes simultaneously at several sanatoriums. The weekly variations show on the whole a distinct parallelism in the patients at different sanatoriums, and this uniformity seems chiefly to be due to changes in the humidity of the air, partly also in the atmospheric temperature. Moreover, there are striking monthly variations in the gain in weight. This gain in weight is much the same winter and spring, rises gradually during the summer and reaches its maximum in September, declining steadily in October and November. Similar monthly variations are, however, to be found in other countries, so that weight maximum in Norway occurs in August, in the remaining part of Europe in September, in Pennsylvania in October, in India in November, and in the Argentine in May. Consequently maximum seems to change in proportion to the degree of latitude of the place, and the monthly variations seem to depend on the orbit of the sun.

Other monthly variations imply that particularly great gain in weight occurs in the months with low atmospheric pressure, medium temperature, medium amount of sunshine and large rain fall, while particularly small gain in weight is found in the months with high atmospheric pressure, slight rain fall and particularly low or particularly high atmospheric temperature, besides a particularly small or particularly large amount of sunshine. A continuation of researches would probably give valuable facts to judge of the significance of the influence of climatic and meteorological conditions on the gain in weight and thereby also on the cure of pulmonary tuberculosis.

Scientific Justification for the Classification of Pulmonary Tuberculosis Into the Open and Closed Forms.—Alfons Winkler (*Wiener klinische Wochenschrift*, August 24, 1922) draws the following conclusions: The classification of pulmonary tuberculosis according to the excretion of bacilli is of practical importance and based scientifically upon such anatomical and clinical foundations that it ought to be developed further and placed on a uniform basis. Such a classification should be made, not as it was heretofore, almost exclusively from bacteriological points of view, but it should be considered chiefly from the clinical points of view. The terms open and closed should be retained until the nomenclature is more uniformly determined. The term infectious instead of open should include not only the lasting obligate, but also the intermittent facultative excretion of bacilli. The term infectious tuberculosis should include all forms, in which there is an open communication between a tuberculous focus and the bronchial tree and in which sputum containing tubercle bacilli is expectorated; this would also include the cases in which the excretion of bacilli has not as yet occurred or has ceased because of a pronounced lung finding or characteristic general condition, but can always begin or cease.

Serodiagnosis of Tuberculosis.—On the basis of his investigations, which included forty-five sera of tuberculous patients and those suspected of being tuberculous and forty-eight control sera, N. Takenomata (*Schweizerische medizinische Wochenschrift*, February 1, 1923) asserts that the complement fixation test is a reaction, which can aid in the establishment of a definite diagnosis in a number of cases. This reaction is usually positive in tuberculosis of the lungs, in tuberculous pleurisy, and also, as it appears, in other tuberculous affections. In the early stage, in a beginning apical infection, as well as in a more advanced stage of tuberculosis, failures occasionally occur, but on the other hand early cases may also react positively. Of the forty-eight control tests, three sera showed a positive reaction, although tuberculosis could be excluded by the clinical finding and, therefore, the possibility of false positive reactions must be borne in mind. There was no occasion to test the value of serodiagnosis systematically in surgical tuberculosis. Only bacillus emulsion preparations should be used as antigen in the complement fixation reaction; the author had good results with the Besredka antigen and also with the bacillus emulsion prepared by himself. The other serologic methods were not reliable or applicable in the form used by the author: the precipitation test was negative and the agglutination test frequently failed in his experiments.

Histological Findings in Chronic Tonsillitis.—Otto Mayer (*Wiener klinische Wochenschrift,* February 8, 1923) endeavors to show that in the tonsils of patients in whom the clinical symptoms and findings of chronic tonsillitis exist, there were also demonstrable pathological histological changes, which must be termed chronic inflammatory. It appears very noteworthy to the author that these inflammatory changes may affect not the entire tonsil, but only circumscribed portions, so that one may speak of chronic inflammatory focal lesions, which were sometimes demonstrable only in serial sections of the tonsils. The author also showed that the tonsillar plugs do not always show trivial and insignificant findings. The author recognizes that the tonsillar plugs may call forth an undeniable defensive reaction on the part of the mucosa of the crypts, in which they lie. The tonsillar plugs consist not only of desquamated epithelium and detritus but they nearly always also contain fungi and numerous other bacteria. The fungi belong to the streptothrix group; the pathogenic actinomyces does not seem to be found here. At the present time it is impossible to say whether these fungi are themselves pathogenic and produce the chronic tonsillitis, or whether they merely prepare the soil for the suppurative bacteria.

Tonsillectomy in Infancy and Childhood.—Earl M. Tarr (*Archives of Pediatrics,* January, 1923) asserts that infection is the prime indication for tonsillectomy. Preoperative study of the cases and caution are vital. A knowledge of the anatomy of the throat is necessary. Correct surgical technic is imperative. Tonsillectomy in children under twelve years of age should be done under general anesthesia. The hospital is the safest place in which to anesthetize the patient and to operate. The choice of instruments is a personal matter. Ninety per cent. of the author's work is done with a modification of the Sluder instrument. To those who do not believe in tonsillectomy for infected tonsils, the author suggests röntgen irradiation as a beneficial treatment, given, of course, by a qualified röntgen therapeutist.

The Tonsils in the Tuberculous.—Maurice Fishberg (*Medical Clinics of North America,* November, 1922) found that pulmonary tuberculosis occurs most often in persons in whom the atrophy of the lymphoid tissue in Waldeyer's tonsillar ring is extreme. When appearing in patients in whom the tonsils are large, in whom the adenoid vegetations in the rhinopharynx are prominent and the lymphoid follicles on the back of the tongue are large, the tuberculous process in the lungs seems to run a mild course and tends to recovery in the vast majority of cases. These patients do well as long as the tonsils and adenoids are not removed surgically. In contrast to these cases, there are those with active and progressive tuberculosis of the lungs, with pale throats, small tonsils, with a lingual tonsil visible only rarely and with the sinus tonsillaris appearing as if evacuated. In fact, laryngeal tuberculosis is rarely associated with large tonsils; the reverse is the rule. The condition of the lymphoid tissue in the throat is, within certain limits, a good prognostic sign. In the vast majority of cases of active tuberculosis, the prognosis is unfavorable when the tonsils are small, the mucous membrane of the rhinopharynx pale and the lymphoid follicles absent; the prognosis is good, on the other hand, in tuberculosis patients with large tonsils, adenoid vegetations and a congested mucous membrane. Tuberculous patients who contract coryza, tonsillitis and rhinopharyngitis, especially of the epidemic type, have a better outlook than those who escape these maladies when exposed to infections.

Asthma, Hay Fever, Nasal Hydrorrhea, and Angioneurotic Edema.—In a partial review of the etiology, Charles B. Williams (*Laryngoscope,* January, 1923) declares that the vasomotor disturbances mentioned in the title are only symptoms of anaphylactic origin, that protein sensitization is responsible for the precipitation of attacks in a large percentage of cases, if not, in fact, the cause in many; that dysfunction of the ductless glands possibly plays an important role; that exposure to cold leads sometimes to a hemoclastic shock, which in turn may precipitate an attack of spasmodic coryza or others of these vasomotor disturbances, and that foci of infection, particularly about the head, should always be searched for when seeking to find the cause for these disturbances.

Essentials in Diagnosis and Treatment of Pulmonary Tuberculosis.—J. H. Stygall (*Journal of the Indiana State Medical Association,* March, 1923) emphasizes certain points. These are: 1. Numerous sputum examinations should be made in all suspicious cases. 2. Pulmonary hemorrhage and pleurisy with effusion are always due to tuberculosis until proved otherwise. 3. Definite, persistent râles or x ray mottling above the second rib or third dorsal spine are always due to tuberculosis except in rare instances. 4. Definite râles at the base with no signs at the tops are not due to tuberculosis unless there is a positive sputum. 5. Absolute rest is the only specific we have for active tuberculosis. 6. Tuberculin should never be given to patients with fever.

Resistance of Tubercle Bacilli to Boiling.—Karl Preis (*Wiener klinische Wochenschrift,* October 26, 1922) has shown that all the acid alcohol fast bacteria known up to the present time are completely decolorized by boiling water within one minute, whereas the tubercle bacillus retains its stain sufficiently even after five minutes. Bovine and avian tubercle bacilli and those from cold blooded animals show a considerably less resistance to boiling than the human type of tubercle bacillus. Specimens (slides) must not be fixed nor excessively heated during the staining process; decolorization should always be done with fresh water and only in metallic vessels. The boiling procedure should be applied only for a closer differentiation between genuine tubercle bacilli and pseudotubercle bacilli.

Treatment of Pneumonia in General Practice.—Warren T. Vaughan (*Southern Medicine and Surgery,* April, 1923) summarizes his routine treatment as follows: adequate rest, both physical and mental, with sedatives when indicated; light diet with forced fluids; daily enemas; sputum typing as early as possible, and administration of immune serum when indicated; use of digitalis, alkalies and oxygen, stressing the use of oxygen early, rather than when the patient is moribund; abundant fresh air for lobar pneumonia, warm fresh air for bronchopneumonia; careful observations for complications both above and below the diaphragm.

SURGERY.

Temporary Plating of Fractures of the Long Bones.—G. H. Edington (*British Medical Journal,* December 23, 1922) asserts that, 1, operative treatment should not be a routine, but properly reserved for cases where nonoperative measures fail to secure restitution of fragments; 2, that temporary plating of the tibia, femur and humerus is a reliable form of internal splinting; 3, that the skin incision should be placed so as not to be in immediate contact with the fracture; 4, that the periosteum should be reflected from the area to which the plate is to be applied so as to encourage the formation of callus; 5, that flat, four hole plates, bent if necessary to fit, and fixed with Lane's screws, give satisfactory results; 6, that external splint support is necessary; 7, that plates and screws are to be removed in from three to four weeks; 8, that looseness or fixity of screws at the time of the removal is in proportion to the reaction or sluggishness of the bone and would seem to be an index to the progress of repair, and 9, that plating does not prevent delayed or nonunion.

Surgical Treatment of Nontraumatic Affections of the Spleen.—James Carslaw (*British Medical Journal,* December 23, 1922) says that the mere finding of splenomegaly is no excuse for operation. Operation is contraindicated in such diseases as malaria and syphilis, although trauma in such diseases may necessitate operation. He is also opposed to operation in leucemia and in Hodgkin's disease. He is not convinced of the necessity of operation in pernicious anemia; certainly not if the spleen is small. Some types of pernicious anemia are more suitable for operation than others. The spleen should be extirpated as soon as possible in splenic anemia, if the patient's health and development are chronically poor, if attacks of splenic pain occur repeatedly, and particularly if the danger of hemorrhage seems to have supervened. For if the disease is allowed to advance too far (cirrhosis of the liver and ascites), the operation is not only more difficult but the chances of ultimate success are diminished. Splenectomy is most successful in cases of acholuric jaundice; mild cases may not, however, require operation. But if hemolysis is extreme and the patient's condition deteriorating, the operation should be recommended, and splenectomy has produced complete and permanent cure.

Surgical Treatment of Tuberculosis of the Lungs.—Hanns Alexander (*Schweizerische medizinische Wochenschrift,* January 18, 1923) warns against the artificial pneumothorax treatment, even in the light cases, because complications occur all too frequently and the duration of the treatment is not diminished. In severe cases interference is justifiable even with a moderately severe involvement of the other side, provided one proceeds very slowly and carefully, that a considerable increase of pressure is never produced, that strict rest in bed is enforced and that the better side is carefully watched. It is always advisable to remove part of the phrenic nerve before doing a thoracoplasty because the resulting spontaneous contraction considerably aids in the result from the thoracoplasty.

Routine Treatment of Fractures by Operative Methods.—As a result of his experience, Archibald Young (*British Medical Journal,* December 23, 1922) arrives at the following conclusions: 1. Silver wire is not very satisfactory for wiring bone fragments; brass wire was found very satisfactory for the fixation of fractures of the jaw, olecranon, patella, clavicle, tibia and the phalanges. 2. For pinning or nailing, the less bulky the pin or nail, the better the result, except for fractures of the epiphysis or neck of the femur and the upper end of the humerus; in fractures of the lower epiphysis of the humerus, small, fine nails are used; "sprigs" or fine wire nails are the best, especially in fracture separations, fractures of the bones of the forearm, fractures of the phalanges and of the metacarpals. 3. Plates and screws have given very satisfactory results in fractures of the clavicle, forearm bones, humerus, femur and tibia. 4. In fractures of the shaft of the femur and other long bones, screws alone are sometimes applicable. 5. Pinning and plating combined give good results in severe fractures of the lower end of the humerus, T shaped, into the elbow joint. 6. The results with ring plates were unsatisfactory.

Chronic Duodenal Ileus.—D. P. D. Wilkie (*British Medical Journal,* December 23, 1922) finds that efficient mobilization of the third and the lower end of the second parts of the duodenum is the secret of easy anastomosis. Although not covered by peritoneum, the duodenum unites without difficulty and he uses only the finest catgut for the anastomosis. The use of a special angled clamp simplifies the operation, but is not essential. In combination with a posterior gastroenterostomy in cases of stenosing duodenal ulcer along the duodenal ileus, the duodenojejunal anastomosis should be planted on the jejunum about six inches beyond the gastroenterostomy. Where an operation on the biliary tract is necessary the duodenojejunostomy should be done first to avoid the possibility of contaminating the sibcolic area.

Dentistry and Medicine*

By LEWELLYS F. BARKER, M.D.,
Baltimore.

Adequately to understand the interrelationship between physicians and dentists we must first have a correct idea regarding the relationship existing between the subjects that these two groups of professional men represent, namely, medicine and dentistry. Medicine, as a science and an art, has as its special province the recognition and treatment of disease. It acquires a knowledge of the laws and principles that hold and it finds out how to apply these principles for the good of patients by inventing useful methods and by seeing to it that its representatives acquire skill and experience in the employment of these inventions in practice. Dentistry has a precisely similar function as regards the teeth and gums; it is to these structures in the mouth what medicine in general is to the whole organism with all its parts. Obviously, then, dentistry is only one of the special divisions of medicine, and the relation of the dentist to the general practitioner of medicine should be much the same as that of any other specialist in a circumscribed domain. In other words, the dentist is comparable to the ophthalmologist, the laryngologist or the otologist, who studies, respectively, diseases of the eye, diseases of the nose and throat, or diseases of the ear.

The layman's idea of the dental specialist is, as a matter of fact, very much like his idea of any medical or surgical specialist. I asked a friend of mine the other day what she thought of dentists as a whole. "Well," she said, "they seem to be people into whose hands you have to put yourself and let them do what they like to you, and half the time you don't know what they're up to." Well, the layman has a similar idea of the medical specialist, say the rhinologist or the gynecologist. "A dentist," my friend went on to say, "looks in your mouth and says, 'How long since you had that work done?' You tell him and he remarks, 'Humph; well, they used to do in that way.'" That reminds one of the nose and throat specialist who looks in your mouth, sees an infected stump of tonsil and remarks, "Yes, they used to take them out that way." Dental specialists sometimes disagree as do other medical specialists. The same friend to whom I have referred has a winter dentist and a summer dentist who have diametrically opposite views on certain dental matters. She tells me that she goes to the one in the summer and to the other in the winter, and that "between the two, things work out very well." This is an attitude toward dentists that also has its counterpart perhaps in the behavior of the layman towards other medical specialists.

If the view that dentistry should be a medical surgical specialty is correct, why is it that the dentist is more sharply marked off from the rest of the medical profession than is the ophthalmologist, the laryngologist or the otologist? To answer this question one must consult the history of the origins of dentistry and of medicine and must consider also the way that medical and dental education respectively have developed. Only so can we reach an understanding of the relative isolation of dentistry from general medicine and from the other medical specialties.

Dentistry as a specialty had a long history before it tended to become separated from medicine. It is recorded that as far back as five hundred years before the Christian era, some medical men devoted themselves especially to dentistry. Dentistry and medicine were, as a matter of fact, closely associated until long after the period of the revival of learning. It was only after surgery and the other medical and surgical specialists had begun to develop more conspicuously that dentistry began to follow an independent path.

This relative independence of the course of dentistry can, I think, be easily explained. In the first place, as operative and prosthetic dentistry gradually developed, the technical complexity of the mechanical manipulations found to be necessary came to require so much attention and devotion on the part of those practising them that no time or energy of the practitioners remained for other kinds of medical work. In the second place, men who worked intensively in general medicine or surgery, or in surgical or

---

*Paper contributed to the survey of the interrelationship between physicians and dentists, at a stated meeting of the New York Academy of Medicine, February 2, 1922.

Copyright, 1923, by A. R. Elliott Publishing Company.

medical specialties, could not master their own subjects and also find time to acquire the technic of dentistry and to make themselves skillful in applying it. Hence physicians and surgeons for the most part neglected dentistry. As a result two groups of dental practitioners began to appear. A smaller group consisted of men who, though trained in general medicine and surgery, finally specialized in dentistry, ultimately restricting their medical and surgical work largely to the dental field; such dental practitioners were true medical specialists, just as are the ophthalmologists, the otologists and the laryngologists of today. The other larger group of dental practitioners of the time of which I speak were not trained in medicine at all; they were mere artisans without theoretical knowledge and without any thorough mechanical training; they practised dentistry crudely, by rule of thumb, in much the same way as the primitive optometrists fitted spectacles, without knowledge of the anatomy, physiology or pathology of the organs upon which they operated. This was the state of affairs that existed some two hundred years ago, when Fauchard, the "father of modern dentistry," published his important treatise entitled *Le chirurgien dentiste ou traité des dents*. From the time of Fauchard on, the practice of dentistry grew ever more specialized and its practitioners became ever more sharply separated from those of general medicine and surgery. A "profession of dentistry" came to be recognized as something separate from the "profession of medicine," the "dentist" belonging to one profession, the "physician" and the surgeon" to another. This divorce of dentistry from medicine, due, as we have seen, partly to the neglect of dentistry by medicine, partly to the rapid technical development of dentistry itself, though in some respects harmful, proved, in reality, to be advantageous, at least in some ways, for the further development of dentistry on its mechanical side. Men to whom dentistry appealed devoted themselves exclusively and wholeheartedly to the development of dental technic and rapidly improved the dental art.

The evolution of dental education has been similar to, and in many respects as interesting as, that of medical education in general. Up to 1840, it was the custom for dental practitioners of ability to pass on their knowledge and skill and their secrets by means of the apprenticeship system. As the methods of modern science, however, came to be applied to the study of the dental tissues, researches on their anatomy, physiology and pathology soon led to the accumulation of a body of knowledge that made it necessary and desirable that dentistry should be systematically, rather than desultorily, taught. The dentist of the newer time needed, in addition to mechanical and manipulative skill, a thorough acquaintance with the anatomy, physiology and pathology of the mouth, and at least some knowledge of the structure, functions and diseases of the rest of the body. The better representatives of dentistry recognized that the apprenticeship system of dental education would no longer suffice; if a narrow artisanry were to be avoided, provision had to be made for a thorough professional education either in medical schools with special departments of dentistry or schools organized especially for instrucion and research in dentistry.

Here in the United States the establishment of dental associations for the advance of dental science "by free communication and interchange of sentiment," and the publication of dental periodicals, helped to force the movement toward the establishment of dental colleges for the systematic education of dentists. The first dental society of the world was, I believe, organized in the city of New York in 1837. Three years later a national association of dentists was formed. In 1839 the *American Journal of Dental Science* appeared, as the first of dental periodicals. And, in 1840, in my own city, the Baltimore College of Dental Surgery had its start, the first of the institutions for the systematic teaching of the science and art of dentistry.

Since 1840 dental associations, dental publications and dental schools have rapidly multiplied, not only in this country but all over the world, and the science and art of dentistry have progressed as rapidly as, if not more rapidly than, many of the other special divisions of medicine. The quality of men entering the dental profession has steadily improved; original researches upon dental problems have attracted many clever minds; and the application of physics, chemistry and mechanics to practical dentistry has resulted in achievements that have astounded the world.

During the past few decades we have been witnessing a revival of the closer relationship between mdicine and dentistry. That relationship ought not to remain clandestine or irregular. It has now reached an intimacy that justifies remarriage. The better dentistry of today demands qualities of mind and heart, a thoroughness of general and special education, a knowledge of facts and principles, and a training in practical technical methods, that are in no way inferior to the requirements in any other medical specialty. Moreover, workers in every branch of medicine must today know how to make use of diagnostic facts in dental domains and should be aware of the possibilities of therapy that dentists control. Furthermore, the dentist who desires to give to his clientele the best results of our present day medical science must have some knowledge of the relation of anomalies and diseases of the teeth to pathological processes elsewhere in the body; he should know, on the one hand, how these processes can affect the teeth and the gums, and, on the other, how diseases of the teeth and the gums may affect the other organs. Practitioners of medicine should know when to ask for a dental consultation and practitioners of dentistry should know when to ask for a medical consultation, and whether a general practitioner, an expert röntgenologist, or some other medical or surgical specialist, can be most helpful to him. Medicine, as regards the various specialties, is advantageously polygamous, and the time has come when dentistry, like other specialties, should again share medicine's "bed and board." For medicine needs dentistry as one of its favorite helpmates. It desires the aid and comfort, not only of the consulting dental diagnostician, but also the advantages derivable from the activities of the dental therapeutic subspecialists, namely, the pyorrhea specialist, the orthodontia specialist, the extracting specialist and the specialist in prosthetic dentistry.

As a working internist, I have been greatly helped by the consultant dental diagnostician, especially when searching for foci of infection that could account for metastatic infections elsewhere in the body (antritis, arthritis, myositis, osteomyelitis, endocarditis, nephritis, neuritis, or iritis), or when seeking the source of an intoxication that might account for a grave anemia, a gastric catarrh, an obscure neuralgia or a general rundown state.

Dental caries, with its sequelæ, is responsible for many human ills, and physicians owe much to dentists for the education of the public regarding its prevention and regarding the necessity for its early treatment where preventive measures have been neglected. You have shown us that its immediate cause lies in acid fermentation in the mouth, the lactic acid produced dissolving out the calcium phosphate and allowing peptonizing and putrefactive bacteria to destroy the decalcified tissue exposed. We believe from our experience that the teeth of certain persons are especially predisposed to caries through faulty inheritance, through the existence of certain physiological states, like pregnancy, and through the occurrence of such diseases as diabetes and anemia.

Physicians, as well as dentists, are also interested in the anomalies of dental development, especially in the hypoplasias of the enamel that are met with in rickets and in tetany, with their peculiar distribution on certain of the teeth; in the delayed eruption of the teeth met with in children suffering from hypothyroidism; in the concave defects of the cutting surface of the permanent incisor teeth in congenital lues; in the erosive caries that attacks the necks of the deciduous teeth in children of feeble constitution; in the occurrence of huge medial and small lateral incisors in status thymicolymphaticus; in the spacing of the medial incisors and, sometimes, of the other teeth in persons in whom the pituitary gland is overactive; as well as in the changes in the gums that are met with in scurvy, in mercurial poisoning, and in lead poisoning. These are only a few of the conditions in the teeth and gums in which the internist and the dentist have a common interest.

If dentists and medical men are to be reciprocally helpful, there must be a greater frankness between them and a greater willingness for cooperation than has hitherto existed. Disagreements regarding facts and principles must be fully discussed in order that right methods of practice may be reached. In this connection I should like to give definite expression to my own ideas regarding the recognition and treatment of oral sepsis. Though I deprecate as much as anyone the unnecessary extracting of teeth, I feel that a grave responsibility is assumed by anyone who advises the retention of diseased teeth when they are a menace to the health of the patient. And in the decision as to whether a tooth dare be retained, the dentist should not be the sole arbiter; nor should the röntgenologist or the physician be the sole arbiter; the opinion of the dentist, the expert röntgenologist and the physician should all carry weight; the responsibility for diagnosis and treatment in dental domains should, today, be shared. There are still too many dentists who seem to be unaware of the diseases and fatalities for which their inadequate treatment of infected teeth and gums have been responsible, still too many who defend modes of dental practice that those better capable of judging unhesitatingly condemn. There are still too many physicians who ignore the dangers of oral sepsis, or who show too much compliance with the foolish whims of patients who beg to retain the infected teeth that injure them. Our better dentists and our better physicians and röntgenologists should arouse public opinion to a degree that will result in the protection of patients from the ignorant and the incompetent.

Let us welcome, then, an ever greater cooperation between the dental specialist, the general practitioner, the röntgenologist, and the other medical and surgical specialists. Whatever will contribute to the advance of dentistry will help medicine as a whole, and medicine in turn must do everything possible to supply facts from the larger domain that may be useful to the dentist in his special branch.

1035 North Calvert Street.

The Relationship Between the Physician and the Dentist*

By C. N. JOHNSON, M.A., L.D.S., D.D.S., M.D.S.,

Chicago.

It is really a noteworthy event when two great societies like the Academy of Medicine and the First District Dental Society of New York join hands in the consideration of so important a subject as the one under discussion this evening, and on behalf of the dental profession outside of New York, I wish to offer my heartiest congratulations to both bodies on this evidence of an altruistic spirit, which I feel certain is destined to result in great benefit to the people who are conjointly served by the physician and the dentist.

Every thinking man in either calling will admit that in the past—particularly the recent past—much harm has resulted to patients through failure of good teamwork between physician and dentist, and it may be profitable to consider briefly some of the circumstances which have led up to the present situation. For many years the dental profession had tried to impress upon medical men the importance of the teeth as factors in health and disease, and it is no disparagement of the medical profession to state that little attention was paid to the matter on their part. They were naturally more concerned with weightier problems—problems which involved the life or death of their patients, such as tuberculosis, appendicitis, carcinoma, and other diseases. But a curious thing happened, which changed the trend of their thoughts, and focused their attention on the teeth. One of their own members, Sir William Hunter of England, came out with a strong statement to the effect that many of the ills from which humanity suffered were traceable directly to oral infection, and cited case after case where clearing up the mouth conditions had resulted in amelioration of the systemic symptoms. And the most curious thing of all is that while Hunter is today credited with being the man who took the initiative in directing the attention of the medical profession to the teeth, the fact remains that the infection to which Hunter alluded is not at all the infection which today seems such an alarming thing to a large number of medical men.

---

*Read before the joint meeting of the Academy of Medicine and the First District Dental Society of the State of New York, February 2, 1922.

What is concerning physicians most at the present time is the possibility of serious trouble from focal infections located out of sight at the apices of the roots of pulpless teeth, while Hunter never alluded in the most remote manner to this source of infection in any of his published reports. What he emphasized was the infection around artificial crowns and bridges inserted by dentists, "gold traps of sepsis," as he termed them, and spoke of the benefits to his patients from swabbing the mouth with antiseptic washes. And in this connection it may not be improper to correct a misconception started by Hunter—possibly in the most innocent way in the world. He was very strong in his invective against what he termed American dentistry as bringing about all of these disastrous results, when as a matter of fact, Hunter was not at all familiar with American dentistry as practised in the better offices in this country. What he saw was the hideous parody on dentistry as produced by men who posed as American dentists in London, but who no more represented the better practitioners of either America or England than the veriest quack represents the splendid practitioners of medicine. This was a misconception to which the conscientious practitioners of dentistry in America never should have been subjected, and yet it came about in such a natural way, and probably with the utter absence of ulterior motive on Hunter's part, that dentists here accepted it with the best grace possible, and with the hope that good would ultimately come from it.

But what concerns us most at this time is the relationship between physicians and dentists in the management of those cases where certain systemic disorders are supposed to be caused by the teeth. As soon as the attention of the medical profession was called to the fact that the teeth were a possible factor in infection they naturally began giving these organs a great deal of consideration. This was perfectly proper because the function of the physician is to cure disease, and yet in the present instance we feel that two errors crept into the situation. One was the fact that in many instances an altogether exaggerated idea of the relationship of the teeth to general disease gained ground, till they were charged with being the cause of every known disorder from premature baldness to ingrowing toenails. This concentration on one idea to the exclusion of a wider vision is not confined to the medical profession. Dentists are fully as prone to it—probably more so—and it is even said to permeate the legal and all other learned professions. Balance seems to be the most difficult thing for men to acquire, and it is without question true that in the present instance many physicians and dentists were thrown completely off their balance. The shameful sacrifice of many serviceable and harmless teeth that has been witnessed in the recent past is not creditable to either medical men or dentists, and it is confidently believed that conferences between the men of both callings, such as the present, will usher in the dawning of a better day.

The second error relates to the fact that physicians did not always take the best means at their command to get at the truth. Their usual procedure was as follows: A person became ill and sought a physician. If the complaint was one which could in any way be traced to infection—and today in the minds of the profession most diseases can be so traced—the teeth were at once suspected because they happened to be in the limelight. Accordingly, the patient was immediately sent to a radiographer for pictures of the teeth, and it was just at this stage that much mischief was inaugurated. The x ray man may have been a physician who in the natural order of things is not intimately informed on the teeth and their supporting structures; he may have been a dentist who is not intimately informed on anything; or he may have been neither physician nor dentist, but merely a man who can make pictures, and who has not given a moment's study to the anatomy of the parts he is portraying. And yet what happens?

Sagely, this x ray man will write a diagnosis on his chart and send it back to the physician. The latter, acknowledging in all sincerity that he cannot interpret radiographs, accepts the findings of the radiographer and straightway sends the patient to an exodontist to have the suspected teeth removed. Following this summary routine many a hapless victim has been bereft of useful teeth, which were altogether harmless, or might have been made so by treatment. And yet in some aspects this routine is a perfectly natural one. The physician wants to see his patient get well, and if what he has heard about the teeth is true, they are very terrible organs. But what he has heard is not all true, and some of his misinformation has come from dentists themselves. For instance, when he is told that a pulpless tooth is a dead tooth, he is seriously misinformed. It was the dentist who first gave this misleading term to the medical profession, and as a dentist I wish to offer an apology to my medical colleagues for this grave error. Doubtless the introduction of the term dead teeth has done much to cloud the issue in the minds of medical men. No conscientious physician wants anything dead in his patient's mouth, and the sooner medical men learn that a pulpless tooth is not a dead tooth, the better it will be for all concerned. The destruction of the pulp removes sensation and sustenance from the dentin, but so long as a living pericemental membrane surrounds the root and attaches the cementum to the alveolar process the tooth cannot properly be called a dead tooth. Medical men should note this fact because of its intimate bearing on the matter under discussion.

We have stated that the routine just referred to is a natural one, because of the physician's desire to get his patient cured, but it has one very serious defect. It leaves out of consideration something that might prove of great advantage in aiding to clear up the situation, namely, consultation with the family dentist. He has records of the case and frequently can throw much light on conditions which otherwise would be obscure. And yet, in too many instances he has been entirely ignored, and the patient has been summarily ordered to have the suspected teeth extracted. What would be thought of the general practitioner of medicine who would refer a patient to a surgeon for the removal of an eye instead of sending the patient to an oculist? Or order the removal of a turbinate without consulting a rhinologist? And yet these men have not been specializing in their work as long as has the dentist in his. Since 1840, when the first dental college was organized, dentists have been studying hard to acquire authentic information regarding the teeth and adjacent structures, and in all modesty we feel that their opinion is entitled to as much respect at least as that of the general practitioner of medicine, whose training along these lines has at the best been very meagre. And yet it is not putting the case too strongly to state that in recent years many practitioners of medicine have been ignoring the dental specialist, and assuming an attitude which is not at all justifiable!

Instances are not rare where patients have been advised by their physician to leave their regular dentist and go to some one who would do the bidding of the medical man when a difference of opinion arose as to the advisability of extracting certain teeth. This might seem a permissible procedure in the protection of the patient provided definite knowledge was accessible today as to the direct relationship between the teeth and remote disturbances, and also provided the physician could interpret radiographs of the teeth more accurately than the dentist. But the last word has not yet been said on the subject of focal infection as it relates to the teeth, and it has yet to be demonstrated that the physician knows more about the teeth than does the dentist. When the time comes—as come it must—that it is possible to differentiate between infections caused by the teeth and those caused by other tissues or organs, there will be greater justification for passing judgment on the teeth as offenders, but until that time comes there should develop a more conservative attitude toward tooth extraction than there has been in the recent past.

It is not with dentists a question of prestige. We are not so much clamoring for our prerogative—legitimate as it might be for us to do that—as we are fighting for the welfare of the patient. And in the past few years patients have suffered untold injustice through faulty points of view on the part of medical men as influenced by an undue concentration on the teeth as the chief factors in causing systemic infection, and on the radiograph as an infallible means of disclosing conditions at the root ends of teeth. The teeth are by no means the sole agency for spreading infection, and the radiograph is by no means infallible in its disclosures. These two facts should sink into the consciousness of every medical man, because they are fundamentally and demonstrably true. Countless hundreds of good serviceable teeth have been sacrificed on the altar of this idea without the slightest resultant benefit to the patient, and many other cases have been reported of recovery from systemic trouble where teeth have been retained, in the face of x ray evidence pointing to the necessity for their removal. Case histories could be recited by the score to support this statement, if space permitted.

Dentists would be the last men to argue that the teeth should be ignored in physical examinations, or to contend that they were not an important factor in health and disease. During the entire history of the profession they have labored to emphasize the significance of the teeth as agencies for good or ill. But their present contention is that in the recent past an undue emphasis has been placed upon the teeth as causative factors in disease, and that the x ray as a diagnostic aid has been magnified out of all proportion to its legitimate possibilities. The x ray does not demonstrate infection, it does not show abscesses, nor does it tell whether or not there are pus pockets at the root ends of teeth. The only thing the x ray does in this connection is to reveal varying degrees of density in the alveolar process around the roots of teeth, and this is of sufficient importance to entitle it to our respect and admiration, without distorting the evidence as has too frequently been done. When a radiolucent area is discovered in a picture at the end of a root, there is no man of sufficient vision to tell whether it means an abscess or whether it is merely a thinning of the bone, which may have occurred years previously when the tooth first lost its pulp, and in which today there is no infection whatever. A diagnosis should never be made on x ray evidence alone—the clinical history of the case being of just as great significance, and sometimes throwing more light on it than the picture itself. We frequently hear the statement made that a photograph will not lie, but as a matter of fact, there is nothing in all human experience that may be made to so misrepresent a fact as a photograph.

In the face of this uncertainty as to what the x ray reveals, the psychology of the situation has been seized upon by too many of our radiographers to unnecessarily frighten people. They write upon their diagnostic charts such terms as abscess, infection, evidence of disease, pus pocket, etc., and when the physician receives this he hands it to the patient. This would be bad enough even if the x ray infallibly demonstrated these things—which it does not.

Think of the psychology of this. Every practising physician knows full well the mental effect on many patients of being informed that they have abscesses or infection sealed up in their jaws. If they never have felt ill before, they begin to feel ill now. And when this is done on any such unreliable evidence as x ray pictures it amounts almost to a crime. It is as bad as some of our socalled health articles in the daily press. The less we tell the laity of the symptoms of disease, the better it is for them. All instruction along legitimate lines on the conservation of health is most commendable and should be published broadcast, but when these articles begin to elaborate on symptoms, they place themselves perilously near the level of the patent medicine advertisement.

This matter of the psychological effect on patients from reading the diagnostic charts of their teeth inscribed by radiographers has assumed so serious an aspect that the practice of writing these terrible terms should be frowned on by all reputable practitioners of either medicine or dentistry. Information of what has supposedly been found may be conveyed to the practitioner without unduly alarming a susceptible patient.

This entire question of the relationship between the physician and dentist is one easy of solution, provided the equity of the situation is recognized by both. We as dentists cheerfully accord to the medical profession a wider range of vision than we possess. Medical men are concerned with the entire physical and mental economy of the patient, while dentists are confined in their ministrations to a limited area of the physical mechanism. Our only contention is that within the limits of this area, our opinions are entitled to as great respect as are those of the medical man—and we might go even further and say, in a proper spirit of modesty, that in matters of detail they are entitled to greater respect. We pledge ourselves to an attitude of the most cordial and helpful cooperation at all times in the effort to clear up obscure conditions, and to aid the physician in ameliorating the ills from which our common humanity suffer. All we ask is that, in the interest of the patient, our help is sought when it is needed.

22 East Washington Street.

Dental Diagnosis*

Its Importance in General Medicine

By W. GILMAN THOMPSON, M.D.,
New York.

Two great discoveries of modern medicine, namely, the causative relationship of focal to general infection and the application of the x ray in diagnosis, have done more than anything else to bring into closer harmony the professions of medicine and dentistry. So long as the possibility of systemic infection from an alveolar abscess remained unsuspected, it made comparatively little difference to the patient whether he went first to his dentist or his doctor, and never having been instructed in regard to this possibility he often failed to mention to one of them that he had visited the other. It is this lack of coordination between the findings of the two professions which heretofore so frequently has proved unfortunate for the patient.

More accurate and detailed knowledge is desirable as to those debilitating systemic diseases, which, either by lowering vitality and resistance to infections, or through altering local secretions in the mouth, tend to accelerate disease processes in connection with the teeth which often, when neglected through the patient's weakness, carelessness, or dread of the dentist's chair, make rapid and extensive progress.

Much might be done to remedy this state of affairs if the physician would give more careful attention to the general appearance of the teeth and gums and in referring the patient to the dentist send with him an abstract of the symptoms. This would doubtless add greatly to the interest of the dentist in the case and stimulate the thoroughness of his work.

On the other hand, in those instances in which the patient applies first to the dentist and conditions are found which are likely to impair digestion, give rise to the swallowing or absorption of pus and germs, or otherwise occasion serious symptoms, the dentist should urge the patient to seek his physician for the purpose of thorough physical examination, and should send with him a detailed statement of the conditions observed and local treatment recommended. All this seems a simple and rational procedure, and yet how seldom it is followed as thoroughly as it should be.

Another matter, the importance of which is so little appreciated, is the great desirability of promoting more frequent general conferences and discussions between dentists and physicians. How rarely are dentists invited to active participation in medical societies, and the reverse is equally true.

It is easy, as it is perhaps invidious, to criticize the shortcomings of others, and upon looking backward in the matter under discussion, I am impressed by my own neglect of patients who have needed this cooperation, before I came to appreciate the increasing value of it. But I am constrained to say that there is still a surprising number of patients who tell me that their dentists have belittled the importance of radiography and have neglected to emphasize the need of constant hygienic care of the mouth, being, it would seem, interested exclusively in the mechanical perfection of their work. In fact, I might multiply instances in which upon referring the patient back for x ray examination, considerable additional trouble has been disclosed.

The paraphrase "Unhealthy lies the tooth that wears the crown" unfortunately is too often true and the patient who proudly displays a series of beautifully gilded teeth is wholly ignorant that there may be whited sepulchres beneath. Moreover, just as in valvular heart disease, the worst lesions may be absolutely unaccompanied by pain throughout their development, so advanced cases of pulp decay, pericemental abscess, bone caries, necrosis and pyorrhea do not necessarily give rise to any local pain or even discomfort whatsoever.

Those systemic diseases or abnormal conditions in which in the absence of other more definite etiology the teeth and gums may be suspected strongly of exerting at least a participatory influence in causation, may be grouped in general as follows:

1. Digestive disorders arising from imperfect mastication and the swallowing of pus and harmful germs.
2. Malnutrition, particularly in young children.

---

*Read before the New York Academy of Medicine, February 2, 1922.

whose first teeth are so likely to be neglected on the ground that they soon will grow a second better set.

3. Neuralgias, neuritis and various forms of tic, all the way from facial spasms and tic douloureux to distal painful neuritis in various parts of the body.

4. Disturbances of the heart action, particularly irregularities of rhythm, more common in the aged, and sometimes mistaken for myocarditis, until treatment of pyorrhea or cleaning up a localized pus focus about the teeth restores the natural cardiac rhythm.

5. Endocarditis, particularly in the young, and the socalled septic endocarditis in older subjects.

6. Anemia, of secondary type, often quite advanced. The causative relationship of periodontal abscess, caries, and similar conditions, to pernicious anemia, while by no means proved, is nevertheless suspicious, for one almost never sees this type of anemia unaccompanied by marked changes of decay among the teeth.

7. Various forms of both acute and chronic arthritis and polyarthritis, and of myositis, formerly classed under the vague title of "rheumatism" and treated by saturation with such remedies as potassium iodide and the salicylates. With these especially, the so-called arthritis deformans should be under suspicion. Whatever view may be held regarding this etiology, it is unusual in my experience to have met with a patient suffering from one of these forms of chronic arthritic disease who could display a fairly normal dental series.

8. Acute septicemia and pyemia, which although fortunately rare in connection with even advanced dental disease, nevertheless include too many cases to admit of longer denial as to etiology. In one such case under personal observation the patient, a man of fifty years acquired a typical septic temperature of many weeks' duration, a trophoneuritis of the leg, pyemic abscess in both legs and a slough of the right arm which extended around nearly two thirds of its circumference and necessitated prolonged subsequent skin grafting. After six months he finally recovered, but when I first saw him his physicians believed him so near death that they feared the shock of even a single tooth extraction. Upon my insistence, however, some half dozen teeth were serially extracted, their abscesses, involving extensive bone absorption, were removed, and the gastritis and extreme anemia with the other symptoms finally yielded to vigorous oral antisepsis. This incident is illustrative of the nearly fatal results which may follow neglect of the tooth brush.

There are other exceptional types of disease in the origin of which the teeth have come under suspicion but the well proved list of maladies definitely originating through diseases of the teeth and contiguous structures is quite long enough to constitute a serious indictment against the lack of appreciation of the importance of mouth hygiene.

It is necessarily admitted that there may be other causes for all the diseases previously mentioned, but when they can be excluded definitely, suspicion reverts to the teeth with greater emphasis. There is at present, in fact, an active rivalry between tonsils and teeth as to their respective ability to interfere with bodily functions remote from those which nature intended them normally to perform, and partisans of one or the other theory are disposed to extend the scriptural injunction, "If thine eye offend thee, pluck it out," to cover the particular structure which for the time interests them. Older members of the medical profession will recall a similar wave of enthusiasm for removing ovaries often in cases in which more mature deliberation and more thorough study would have resulted, if not in the verdict "not guilty" in a verdict of "not proved."

It is furthermore admitted necessarily that all manner of advanced decay of the teeth with extension to contiguous structures exists frequently without any discoverable systemic symptoms whatsoever. Nitroglycerine burns quite slowly and harmlessly in the open air, but how differently it behaves in a confined space, just as pus may react differently on a free surface than in a confined space.

Another phase of this topic which often fails of appreciation by the medical, or rather surgical practitioner, is the fact that during prolonged convalescence after serious operation there is likely to be rapid advance in disease foci in and around the teeth, which may be due both to the lowered vitality of the patient and to his inability, through weakness, properly to observe oral cleanliness. For this reason, whenever time permits, before a contemplated operation of gravity it is most necessary to clean house, so to speak, to the end that convalescence be not prolonged through the flaring up of a periodontal abscess, with toothache and neuralgia, or the indigestion and distaste for food which a poorly conditioned mouth engenders. This matter has for some time been recognized at the Mayo Clinic and other large clinics, but it needs much reiteration for the profession at large. It has been emphasized longer in the prenatal care of the expectant mother, but here also too much emphasis cannot be placed upon its importance.

In illustration I recall a recent case of a patient who, having a protracted convalescence after a complicated prostatectomy, presented so painful a molar abscess that he was obliged to drag himself out to the dentist before he was really fit to move. Yet not one of his half dozen otherwise distinguished physicians and surgeons had suggested to him to have his teeth examined prior to operation, although there had been ample time to do so, and being a physician himself he had given no thought to the matter;

Truman W. Brophy has well written, "The teeth are the least understood and most neglected of all the tissues of the body." This being admitted, their wholesale extraction as the shortest way out of a difficulty is greatly to be deprecated wherever conservative treatment has reasonable chance of success. To this end much more study should be given to the behavior under varying conditions of the many varieties of germs which inhabit the mouth, especially to determine those conditions under which many of these germs take on aspects of virulence after long periods of quiescence. For example, in those two diseases, diabetes and pernicious anemia, in which deterioration of the teeth constantly becomes so rapid, an intensive research into the problems involved might readily yield results of great interest and importance and establish principles of far reaching application. Dentists might well give more practical and individual study to the problems of bacteriology and particularly if encouraged as they should be, by the active cooperation of physicians and pathologists.

Another subject which should be investigated experimentally upon a large scale is the effect of diet, particularly in the young, in determining different types of dental disease. Experiments of this sort which are being made upon animals at one of the prominent hygienic laboratories of the country already give promise of surprisingly important results.

Finally, the undergraduate medical curriculum should include much more systematic instruction in the rudiments of dental pathology, and surgery, emphasizing the now well established relationship between dental and systemic diseases.

17 West Fifty-third Street.

The Interrelationship of the Physician and the Dentist*

By LEROY M. S. MINER, M.D., D.M.D.,
Boston.

Dentistry occupies a curious position in its relation to medicine. Admittedly, the function of the present day dentist is to preserve the health of the tissues of the mouth, and to care for these tissues when they have become diseased. By virtue of this service, dentistry should be as much a genuine part of the art and science of medicine as are the definitely accepted specialties in medicine that restrict their attention to anatomical units, as, for example, otology and ophthalmology.

We see and hear frequently in these days the statement that dentistry is a specialty in medicine. True as this may be in theory, in the conduct of everyday practice, dentistry today is not a specialty in medicine as we commonly understand the term, and is not so considered in the mind of the average physician, nor even, I venture to say, in the mind of the average dentist. Separate professional societies and separate state boards of examiners for licensing to practise definitely differentiate the two. In the same breath that the statement is made that dentistry is a specialty of medicine, we hear that there should be closer cooperation between the two professions, medicine and dentistry. Here again the phrase medicine and dentistry is quite suggestive of the distinction that actually exists. We never hear of medicine and otology, or medicine and ophthalmology, simply because these and other specialties are vital parts of and therefore included in what we know as the practice of medicine. And so dentistry occupies the curious position of being a distinct profession, and yet so closely related to medicine that few would deny that it should be a specialty in that profession. Like the poor relation, dentistry has to be endured by medicine because of the close relationship, but is not altogether welcome as an equal or as a real member of the medical family.

The subject of the relationship of diseased teeth to various systemic diseases, and the opposite of this, namely, the relationship of certain systemic diseases to disturbances in the oral cavity (concerning which we know but little), have awakened the thinking man in both medicine and dentistry to the great need of the correlation of their respective fields of work. Charles Mayo crystallized the matter when he said that the next great advance in medicine must be made by the dentist. It must be evident that to accomplish this, and to solve successfully the many common problems that are facing us, necessitate genuine cooperation between physician and dentist. Only by cooperation can each learn and better appreciate the problems of the other.

And yet in spite of this evident need, I think it is fair to say that the interrelationship that we are discussing does not exist, either educationally or in the conduct of everyday practice, except perhaps in a small way in our larger cities. Certainly the relation of physicians to dentists throughout the country generally leaves much to be desired, and could be greatly improved to the advantage of both.

The truth frankly stated is that the physician generally has a supercilious attitude toward the dentist. This is so definitely apparent that there are men in this city and other large cities practising oral medicine or surgery, and who though trained in both medicine and dentistry, and licensed to practice both, find it to their advantage to make use only of the M. D. after their names. One man here in New York said to me that the use of his dental degree was a distinct handicap, and he had therefore dropped it, and this, in a day when men are so proud to put after their names F. A. C. S. and other letters indicating professional attainment.

What is the cause of this attitude? Of the various factors that might be mentioned probably the most important are, first, the nature of the dentist's service, and second, the educational differences that exist.

As regards the nature of the dentist's work, until recently it always had been considered by people generally a mechanical profession. If a young man indicated a desire to study dentistry, the questions always asked were, Is he mechanical? Can he use his hands? The teaching and training in the dental schools had been directed with the principal object in view of developing operative dexterity in filling teeth, making bridges and plates, and extracting. The reputation for skill that American dentistry possessed indicated how well the dental schools had done their work. From an operative viewpoint, the recent graduate of a good dental school was better fitted to start practice than was the recent graduate in medicine, but because of the fact that dentistry had been so mechanical and therefore not involving life and limb, it had been considered by the physician and by the public, too, of secondary importance.

---

*Read before the New York Academy of Medicine and the First District Dental Society of New York, February 2, 1922.

I have used the past tense advisedly in this description for today we are realizing that dental work under some conditions may affect profoundly the life and limb of the patient. Desirable and praiseworthy as mechanical skill may be, the present day dentist who has no broader outlook than this has indeed a limited horizon and has little conception of what the practice of dentistry today really means, nor does he realize the tremendous responsibilities and possibilities that dentistry now faces because of the present conception of the relation of the tissues of the mouth in health and in disease to other structures of the body.

In this connection the educational problem becomes of serious importance. It was natural with only the mechanical aspects to develop, and with no conception of a medical relationship, that schools should have been founded for teaching dentistry, having no connection with medical schools. The result has been that medical and dental education has grown and developed along parallel lines with but few points of contact. The formation of its own state and national organizations has contributed to the further development of dentistry as a distinct profession.

The clean cut separation of medicine and dentistry has been an obstacle in the path of progress. In the light of our present knowledge it is quite clear that the physician knows too little dentistry and the dentist knows too little medicine. Each lacks, therefore, the necessary prospective which might be less noticeable if there was more educational cooperation. Diseases of the mouth and teeth have received practically no attention in our medical school curricula. Some physicians even seem to take pride in their ignorance of dental conditions, as though they were unworthy of their attention.

I cannot help but believe that had physicians as a class known more about dentistry, the problems in connection with dental focal infection would have been handled much more intelligently than they have been. The great need of a chair in stomatology or odontology in our medical schools is so apparent that some medical schools have already established it. The function of such a professor is to correlate dental disease in its various aspects to the systemic conditions that the physician must take care of. This is by no means limited, moreover, to the matter of focal infection.

Dentistry, on the other hand, has suffered from an intensive specialized training. Without a sufficient training in the fundamental sciences, the dentist has lacked the ability to correlate adequately his work with the work of the general medical man or the medical specialist. There are still those who feel that this is not a necessary part of the dentist's function and that our dental schools should continue to devote most of their attention to mechanics and to the development of manipulative dexterity.

Admitting that this is important for the dentist, is it not equally so for the surgeon? The general principle, that the broader the dental training the safer the dentist, particularly in matters of judgment, is a sound one. If more attention was paid to the fundamental sciences allied to medicine in the process of dental education the dentist would be better equipped and could meet the medical man on his own plane. I could risk the development of his manual dexterity. He would acquire it just as does the surgeon.

In point of requirements, dentistry has always been a little behind the medical requirements. Today, with the advanced requirements of one year of college work and four years in the dental school, dentistry is still one year behind the minimum requirements of medicine. Even were they equal, however, dentistry still lacks the medical degree which has been regarded with so much respect down through the ages. I hope to see the day when a doctorate of medicine will be a part of the necessary equipment of the dentist, not alone for the mere possession of it, which permits of the formation of valuable associations, but for the training it represents in branches of science that can be so valuable to the dentist.

The lack of an educational cooperation between medicine and dentistry is quite definite as regards admittance to medical schools. If a man, who has spent four years in a dental school and has received his degree, desires further training and wants to become a candidate for a doctorate in medicine, he finds that no allowance whatever will be given him for his training in dentistry and that four or six years if he has had no college work will be necessary to accomplish his desire. This indicates how far from being a specialty in medicine dentistry really is in the minds of those responsible for standards in medical education. There are, however, many interested in medical education who feel that this inflexible rule could be materially modified to the great benefit of dentistry without injuring medical standards.

In this short paper little more than generalizations can be made. In pointing out some of the weaknesses of the interrelationship of the physician and dentist the educational value to both that would ensue from their correction must be apparent.

I cannot refrain from discussing briefly one concrete problem that is second to none in its importance. I refer to dental caries. So prevalent is this condition that some one has called it the people's disease. It is the starting point of a large part of our dental diseases, and if the cause of this condition could be found, it would obviate the necessity of so much reparative dentistry and solve the problem that some have made so much of, insisting that dental requirements should be kept low in order to have an adequate supply of men to do the repair work made necessary by the ravages of decay. Miller's researches have for many years been accepted. Today, while his theory of decay remains sound up to a certain point, we know the whole truth is not contained therein. The relation of diet to this condition has been studied by some of our best dental research men, and many valuable experiments have been made, but there remains much to be done before the subject is conquered. That dental caries is in a large measure no more than a symptom of some metabolic fault, seems not improbable. Hence, if there is any subject in the world where active cooperation between physician and dentist would be of value from many viewpoints it is this. Active association of the dentist in community health organizations, particularly in the prenatal and pediatric clinics, should in time give us valuable information. But the dentist associated with this work must of necessity have a good training in the fundamentals.

In summing up the subject I cannot do better than quote from a recent report of the committee appointed by the overseers of Harvard University to visit its own dental school. Professor William Sidney Thayer, of John Hopkins University, was chairman of the committee. Some of the significant statements are given herewith.

"Dentistry should be regarded fundamentally as a special branch of surgery. Further and more intimate cooperation between the departments of medicine and dentistry, not only at Harvard University, but elsewhere throughout the country, should ultimately bring this about."

"The ophthalmologist and the physician and surgeon," writes Dr. Thayer, "meet on common ground: they are members of the same medical societies. Their subjects are discussed at common meetings. The dentist and the physician do not meet on the same common ground. This is unfortunate for the physician, for the dentist, and for the patient. The circumstance that the requirements for admission to dental schools have been lower, and the circumstance that the amount of general and medical education demanded of the dentist has been less than that demanded of the physician and surgeon, have worked to place the dentist at a disadvantage in the medical and general community. This has not only been a disadvantage to the dentist, it has been a very real disadvantage to the medical profession. It is, we believe, of importance to medicine that the time may come when the requirements for a dental and a medical education may be the same; when dentistry may become, as it should be eventually, one of the specialties of surgery." Dr. Thayer speaks of the new requirements for entrance to the Harvard Dental School, which now demand not only a high school education, but also a year of college work, as "distinctly a step forward," and he continues, "As the years go by the importance of that branch of surgery practised by the dentist becomes more and more evident, and the interdependence of dentistry and the other branches of the art of medicine and surgery clearer. . . .

"It is believed by many that the position of dentistry in the community is in some ways anomalous. The work of the dentist while in part given to small details in the care of the teeth, extends insensibly into problems of medicine and surgery of considerably greater magnitude. There are many questions relating to the pathology of the mouth and teeth of great importance to the human economy about which there is little fundamental knowledge; such, for instance, as the causes of dental erosion and caries and their possible correlation with other local and general pathological processes in the individual. These are important and attractive problems for investigation. The adequate study of some of these problems calls for men with a wider training than is given to the ordinary dentist, and the questions involved are of considerable importance to medicine as a whole."

The report suggests the acquisition of means for the establishment of further university professorships in dentistry, and for the establishment of special fellowships or research funds providing for the study of pathological problems related to diseases of the mouth and teeth, and the further suggestion is made that students in the dental school might well spend a fifth year of study in acquiring the basis of a general medical and surgical training together with such special training as would justify the additional degree of doctor of dental science.

In conclusion, when the time comes that both physician and dentist throughout the land thoroughly appreciate the need of a close interrelationship and when in the course of that interrelationship they meet on an equal footing, then may we expect to see real progress. Under such conditions the solution of the cause of dental caries may be expected, and this discovery will take its place along with the other great discoveries in medicine.

153 Newbury Street.

Cause and Effect of Malocclusion of the Teeth

By L. M. WAUGH, D.D.S., F.A.C.D.,
New York,
Professor of Orthodontics, Columbia University.

It will be my aim in this résumé to consider well established practical facts as generally recognized and accepted by specialists in orthodontics and to avoid discussion of etiological factors and their sequelæ which are as yet of a more or less problematical nature.

In the study of malocclusion of the teeth, as with all pathological conditions, it will be necessary to review the normal as the basis from which the abnormal may be judged. The term malocclusion does not in itself imply disease but rather an abnormal condition that is a progressive favoring factor. While abnormality and deformity may exist without disease in a general sense, this applies less strictly to the mouth than to other parts of the body, because the rugged stress necessitated by the performance of function makes it essential, if a state of health with maximum efficiency is to be maintained, that the teeth be normal in form and in position. Therefore, a brief general review of normal occlusion will be in order.

In the normal human dentition each tooth occludes with two teeth of the opposite jaw, except the lower central incisors and the upper last molars. The cusps or eminences of the molars and premolars fit into corresponding depressions of certain teeth of the opposite jaw, with machinelike precision and regularity. By this means a series of mortars and pestles is provided for the trituration of foodstuffs. The upper incisors and canines form a slightly larger curve than the lowers, the labial surfaces of which approximate the lingual surfaces of the uppers for about one fifth their length. By this relation they can incise or shear the food. This precise interdigitation is essential also to the longevity of the teeth. By this provision, every time the jaws are closed the teeth come to a definite and positive resting place, a condition essential to the maintenance of health in the supporting structures of the teeth.

Any perversion of this normal relationship is termed a malocclusion whether of the deciduous or of the socalled permanent denture. The deciduous teeth have two principal functions, 1, that of mastication, and 2, that of influencing the development of the bones of the face and cranium.

A malocclusion of these teeth must ultimately be regarded as the result of inharmonious development of the jaws and teeth, or in other words, a perversion of the normal growth of this region, whether of intrinsic or extrinsic origin.

The influence of heredity is much discussed in orthodontics. Some of the foremost specialists ridicule the suggestion that it can enter into the problem. Much has been written about the child inheriting the large teeth of one parent and the small jaws of the other, but the possibility of this is denied by a group of the leaders. They ask that proof be furnished and it must be admitted that it has not been convincingly brought forth. They also point to the fact that as a result of mild, continuous, mechanical stimulation it is possible to grow from a small jaw one of ample size to accommodate, in normal occlusion, the relatively large and malposed teeth. This result is being brought about in daily practice by untold numbers of orthodontic specialists. We, however, believe with the other group that heredity is a factor. Nature always builds toward a type. Supernumerary teeth and missing tooth follicles appear with impressive regularity in families, sometimes skipping a generation and reappearing subsequently. The influence of heredity probably lies in the germ plasm and is inherent in the chromosomes. With this brief allusion to heredity, we shall refer to factors that are better understood.

It will be best to review briefly the development of the mandible and the teeth. The mandible at birth is practically straight. With the eruption of the teeth, the ramus develops and the body of the mandible undergoes growth. This is manifest by a thickening of the bone from the mental foramen to the alveolar border and the ramus begins to approach a right angle with the body of the bone. The mandible performs two functions: a, respiratory, and b, masticatory. Both influence its development. At birth all of the teeth have begun to develop except the permanent second and third molars. The tooth germs lie embedded in the cancellous interior of the jaws. In the upper, they occupy almost all of the area to the floor of the nose and orbit. The maxillary sinus or antrum develops later. Each tooth germ occupies a separate crypt, and as the germ grows the pressure it exerts pushes the crypt deeper into the cancellous bone. Coincident with the growth of the tooth germs is that of the tongue and associated parts, these exerting pressure upon adjacent surfaces of the bone. The attached muscles transmit force to the periosteum and bone, and in the acts of mastication, deglutition and respiration these serve as a mechanical stimulus to bone growth. These forces must act in harmony or the teeth when they erupt may meet outside the influence of the proper inclined planes of their antagonists and cause the beginnings of a malocclusion. Any malocclusion disturbs the balance of distribution of force and results in a disturbance of bone development which, according to Noyes "progresses during the entire period of development."

Usually between the seventh and ninth months the central incisors begin to appear. As the tooth lengthens, the bone from the side of the crypt grows into the wall of the alveolus. As the tooth moves occlusally, the root gradually lengthens. At the same time the tongue and lips exert pressure and influence the direction of bone growth. The jaw thickens and grows forward and outward. The growth of each successive tooth is exerting pressure upon those previously erupted, causing them to move more to the occlusal. This is repeated, until at about two and one half to three years, the twenty deciduous teeth are in place and all normally in proximal contact. The stimulus provided by proper mastication and by the constantly growing follicles of the permanent teeth brings about sufficient growth so that at five to six years of age, spaces have appeared between all of the teeth except the molars. *Spacing of the incisors and canines at this age is just as much normal and to be desired as is the enduring contact in the permanent set.* If this spacing does not occur it indicates improper development of the jaw which must be corrected by orthodontic means or the permanent teeth will erupt either in rotation or out of the line of the arch. All of the crowns of the teeth are as large when they peep through the gum as they will ever be. They do not increase in width afterward, therefore enlargement of the jaw between the anterior deciduous teeth causing them to space is of utmost importance.

If, for any reason, a deciduous tooth must be permanently lost, immediate means should be provided for maintaining the space, otherwise the teeth will shift together. This may lead to impaction of the developing permanent tooth or of its being forced out of line of the arch, and what is more important, if left uncorrected, it will tend to allow the developing permanent first molars to take positions anterior to the normal. Each deciduous tooth has a definite function in the development of normal occlusion of the permanent set. In the order of their importance they are: first, the canines; second, the molars, and last, the incisors, the upper being less necessary than the lowers.

The importance of maintaining in harmony all developmental forces at this tender age becomes apparent when considering the growth of the brain. At birth its average weight is 371 grams, at six years about the time the first of the deciduous teeth begins to be replaced, it averages 1,360 grams. This shows a growth of almost 1,000 grams during the first six years after birth. At nineteen years, the average brain weighs 1,400 grams, or a growth of only forty grams during the thirteen years elapsing between the sixth and nineteenth years. The increase in general body weight during the presence of the deciduous dentition is also striking. From the age at which it becomes complete to the time when all have been replaced, the weight of the average normal child has increased approximately threefold. The permanent first molars appear about the sixth to seventh year to the distal of all the deciduous teeth. The lower usually slightly precede the upper. These four teeth are the first of the permanent teeth to erupt and are of utmost importance, both in maintaining the relations of the jaws and in doing the principal masticating while the deciduous teeth are being replaced by their permanent successors. An abnormal relation of these teeth will entirely change the direction of forces which will be manifested by a modification of bone development. The permanent central incisors are now replacing the deciduous ones. If proper developmental spacing of the anterior deciduous teeth took place, these teeth should erupt in normal position. The lateral incisors will follow in a similar manner at about the seventh to the ninth year, the proximal surfaces meeting normally with the centrals will exert pressure laterally and aid in stimulating the growth of bone needed for jaw development. Proper proximal contact is essential to proper jaw enlargement. Then will follow in similar manner the first premolar at about the ninth to tenth year, the second premolar at ten to twelve years, the canine at eleven to thirteen years, and permanent second molar at about the twelfth to the fourteenth year. If all forces have acted normally, the teeth will have come to their proper positions. One tooth rotated or out of proper alignment can cause lack of proper development of the region a condition that is usually progressively aggravated with the eruption of the succeeding teeth. At thirteen to fifteen years of age there should be twenty-eight permanent teeth in full eruption. Even though these be in normal occlusion, it not infrequently happens that the third molars or wisdom teeth in their growth and eruption at from the sixteenth to the twenty-fourth year, because of lack of jaw area for them, will so crowd that the pressure will unbalance occlusion, sometimes producing a rotation and overlapping of the incisors and canines. This is more marked when the arches are inclined to narrowness and occurs more frequently with the lowers. Unfortunately, we find that less than ten per cent. of persons have normal occlusion without orthodontic assistance.

The too long retention of deciduous teeth is equally as harmful as premature loss. Sometimes their roots are resorbed very slowly and the tooth is too long retained. This is likely to be the case when the pulp has become diseased or has died. Again the tooth may become wedged between erupted permanent teeth. By means of a radiogram it can be determined whether the permanent tooth is developing, and if so the deciduous tooth should be extracted without delay. In fact, we believe it to be the best practice to have very badly decayed and abscessing deciduous teeth removed without delay and means immediately provided for the prevention of the closing of the space, in cases when the permanent successor is not about to erupt. General systemic disturbances are just as possible from diseased deciduous teeth as from permanent ones. In our opinion this fact is too frequently overlooked.

A retained deciduous tooth should not be removed until a radiogram proves the presence or absence of the developing permanent successor. When conditions necessitate the extraction of permanent teeth, means for retaining the space thus made should almost immediately be provided. If this is not done, the teeth adjoining the space will shift and incline toward each other, resulting invariably in an unbalancing of occlusion which becomes progressively more serious with the advance of years. This is a principle which cannot be violated without serious consequences. The one exception is with the extraction of the third or last molars in the arch, and even with these harmful results sometimes follow.

Bone development in the jaws is largely dependent upon proper mastication on the sound physiological principle that "the use of an organ determines its strength." Therefore, the teeth should at all times be in such condition that thorough mastication can take place in entire comfort and the child should then be encouraged to eat coarse and fibrous foods and to make thorough use of the teeth.

Habit is one of the early causes to which attention should be given. Such practices as thumb sucking, lip biting, tongue biting, drawing or sucking the cheeks between the teeth, and others should be corrected, if possible, as soon as observed. The artificial pacifier is potent for much harm. All of these habits tend to mould the jaws into an abnormal form favoring malocclusion. The physician sees these little patients long before the specialist and it is the former who must observe and advise the parent. The orthodontist can by placing a simple appliance often aid materially in breaking the habit. This can often be worn as early as two and one half years. Such habits as persistent resting of the cheek against the hand, as in study, may cause marked asymmetry of the jaw with consequent disturbance of occlusion. Correction of bad habits must be made principally by strengthening the will of the patient.

Adenoid vegetations superinduce mouth breathing and produce a misshaping of the upper jaw. The mouth of a child held habitually open, as in mouth breathing, causes an abnormal muscle pull in the cheeks, thereby bringing pressure in the molar and premolar regions. This tends to cause a narrowing of the jaws and teeth. In the upper the hard palate becomes arched abnormally high. This frequently results in inflection of the nasal septum, the combined malformation producing diminution in the size of the air passages of the nose with consequent impairment of breathing. The correction of this condition often results in most gratifying improvement in the health of the patient. Abnormal tonsillar conditions tend to cause the patient to protrude the mandible in an effort to obtain more throat space for breathing. If uncorrected, the mandible and teeth tend to take on a permanent anterior relationship, producing a prognathous or undershot jaw.

Malocclusion is the most potent factor in the production of diseases of the supporting structures of the teeth. The condition militates against proper mastication. It prevents thorough natural and artificial cleansing of the teeth, thus favoring caries and the abnormal contacts in closure of the teeth result in shock and injury to the peridental membranes, alveolar bone and overlying tissues.

We shall consider briefly the last. This condition has been given by Paul R. Stillman the expressive name "traumatic occlusion." If permitted to persist it may lead to atrophy of the supporting tissues and will lessen their resistance to invasion by pathogenic microorganisms. Periodontoclasia or socalled pyorrhea, or Riggs's disease, must be regarded as only a symptom. The disease proper must be determined and the cause removed if the condition is to be remedied. It is variously estimated by authorities that in seventy to eighty per cent. of cases the cause is primarily a malocclusion and improper restoration of tooth form about the gingival tissues. The subgingival area is the vulnerable point, and it is here that the incipient stage of disease of the soft tissues most commonly takes place. The correction of the malocclusion is a prerequisite to successful treatment of periodontal disease.

Unerupted and impacted teeth, while not strictly within the scope of the title, are practically always associated with malocclusion, except when the offender is a supernumerary. Nervous disturbances are a frequent result and may range from a mild irritability and melancholia through the many manifestations even to violent dementia.

There is more that could be written. The important practical considerations have, however, been included. It will, I feel, be evident that malocclusion can be a potent causative factor in the inception of many bodily disturbances both local and general, ranging in severity from the mildest to the most severe. Malocclusion is an abnormal relationship of the teeth that need not be carried into adult life. The condition can, in all cases, be greatly improved and in the vast majority completely corrected. This can most easily and best be done in the period of greatest natural development of the jaws and teeth which takes place from the eighth to the twelfth year. Many conditions should be treated earlier.

It must be evident that malocclusion may become a menace to health and that teeth in normal occlusion are in that relationship which insures a maximum degree of oral health for the greatest number of years to contribute their part to the bodily health and therefore, to the efficiency and happiness of the person.

Health, Sickness and Death as Related to Dental Infections*

By GILMAN OSGOOD, M.D.,

Rockland, Mass.

I present this paper by reason of my interest in the practical application of the knowledge that infection, developed in and about the teeth, finds a port of entry into the body second to none in importance. Although the tonsils and other avenues are of great moment I shall confine myself to a consideration of the dental infections.

Seven years ago I thought the teeth of comparatively little importance as factors in the etiology of disease, and my present beliefs were gradually developed by observing the effects of teeth extraction on existing disease.

I have sometimes thought the general practitioner is looked upon with suspicion by the specialist, who thinks his lack of knowledge of certain subjects makes him an unsafe interpreter of events, and this may to a certain extent be true, for his work is not ultrascientific—but, on the other hand, his daily observations, which bring into view many things denied the specialist, and include a survey of all branches of medicine, inevitably cause him to make certain deductions from this panorama of events.

An indictment has been found against the tooth and I appear for the prosecution. In courts of law circumstantial evidence is the strongest kind of evidence; it is the inference of fact or facts from existing facts and is more trustworthy in many cases than the spoken words of human beings. I have a few links in the chain of evidence, which, taken separately, may be of little value, but when connected with other links and viewed as a whole are worthy of consideration.

A comprehensive knowledge of any subject is acquired by study of fundamentals, and so if it is true that the origin of many diseases is from infection in and about the teeth, it is selfevident that those who have lived the greater part of their lives without teeth, except the substitutes provided by the dentist's art, should be comparatively free from these diseases.

The incentive for this study came from observing an elderly man in my office last fall. He had had all his teeth extracted when a young man, had always rejoiced in the change to false teeth, and had enjoyed good health. He became a very successful business man, but his activities were not confined to his business and he became expert in antiques and oriental rugs. His agility and keenness of mental vision caused me to observe him with extraordinary interest, and I said to myself—the dentist who extracted your teeth committed a crime, in the eyes of some men of today, but I should like to know how you would appear if the dentist, instead of extracting your teeth, had repaired them with fillings, crowns and bridge work, devitalizing a few during the reconstruction.

I then decided to seek out others who have false teeth and now have records of over one hundred people who have had one or both sets of teeth extracted at different periods of their lives, and have studied the results of such extractions in relation to the general health of these individuals.

Minor details are not included in these histories and when it is a matter of common knowledge that a person has always enjoyed good health, he is eligible for these purposes of study. Some of these people have probably had ailments they did not consider worthy of mention or in their advancing years had forgotten.

---

*Read before the Boston Dental Improvement Society, April 11, 1922.

Class I includes thirty-three who had all their teeth out between the ages of fifteen and twenty-five. The present ages of those living, including the ages of four at death, are as follows:

25 to 30— 2
30 to 40— 2
40 to 50— 5
50 to 60— 7
60 to 70—11
70 to 80— 4
80 to 90— 2

The four not living attained the ages of sixty-eight (two), seventy-five, and eighty-nine. The causes of death being senility, septic poisoning, cancer of bowel and heart disease.

Class II includes fifty-three who had all their teeth extracted between the ages of twenty-five and fifty. The present ages of those living, including the ages of seven at time of death, are as follows:

30 to 40— 1
40 to 50— 3
50 to 60— 8
60 to 70—12
70 to 80—13
80 to 90—13
90 to 100—3

The seven not living attained the ages of sixty-five, seventy, seventy-five, eighty (two), eighty-seven, and ninety-three. The causes of death being senility (three), pneumonia, heart disease, fracture of hip and sudden death, one each.

Class III includes twenty-four who had all upper teeth extracted between the ages of ten and forty-five and many of these have no lower molars. The present ages of those living, including the age of one at death, who died at sixty-eight from diabetes, are as follows:

40 to 50— 3
50 to 60— 6
60 to 70— 9
70 to 80— 5
80 to 90— 1

Those in Class I have been remarkably free from sickness of all kinds. We do not find lesions of nervous systems, digestive disturbances, rheumatism or known valvular heart lesions, which were nonexistent at time teeth were extracted.

In those living, excluding minor ailments, sickness incident to childbirth and senile changes, the only illnesses recorded are operations for hemorrhoids, benign tumor of breast, exploratory laparotomy (no pathology), one each; "stoppage," varicose veins, fracture of patella, one each; pneumonia, two, and a few cases of illness where no diagnosis was made.

In the list of dead was one in whom there developed a heart lesion when twenty which was about the time her teeth were extracted. She was left a widow with five children at twenty-five, worked hard, recovered from double pneumonia at sixty-five and died at sixty-eight. In these cases resistance to intercurrent diseases was apparent by their rarity.

In Class II many have enjoyed the same good health as did those in Class I. In only one case did rheumatic fever first occur after all teeth had been extracted, appearing at the age of thirty-six, two years after the last extraction, and was coincident with tonsillitis.

In a few cases we find rheumatic manifestations appearing from time to time, where it had existed previous to extraction and this was also true of hepatic colic.

The earlier in life teeth were extracted, the less likelihood of recurrence of these troubles. The complete disappearance of rheumatism, neuritis, headaches, back troubles, nervous and digestive disturbances was remarkable.

We hear so much about the necessity of preserving the teeth, as they are all important in the process of digestion, and have known so many instances of cessation of these troubles following the extraction of teeth, we ask the question: Is the dependence on teeth for good digestion a matter of knowledge, or is it a matter of opinion?

So rarely have I obtained history of tonsillitis, I infer such is usually secondary to infected teeth.

Class III shows many who have been remarkably free from sickness, but there are several instances where illness has occurred, such as do not appear in Class I, which are accounted for by existing infection in the lower jaw.

The cases I have found of people advanced in years, with perfect teeth, are so few that it would be unfair to draw deductions from them, but in the three years of which I have reports, they enjoyed the same good health as did those in Class I.

The resistance of some people to disease is so great that it will give the critic opportunity to cite cases of aged people who have always had infection in the mouth, but I do not think anyone would wish to argue that the existence of such infection was not without danger, any more than one would maintain that the Spirocheta pallida, which had existed in one's blood for years, without apparent illness, could do no harm.

Just why primary invasion is not always to be followed by infection is a question yet to be answered; but the integrity of the epithelial linings in the various parts of the body are assumed to be the reason why certain persons are immune.

A study of these cases induces me to say, show me a person who for years has harbored no infection in or about his teeth and I will show you a person who has enjoyed good health.

When we see patients seriously ill, examination of the teeth will frequently disclose some evidence of infection in the oral cavity. If the illness has been of short duration, we can expect a rapid recovery by removal of infectious foci.

Those who are neurasthenic or otherwise mentally disturbed; those suffering from lassitude with no pleasure in their work; those with anemia; those with back troubles, whose accompanying scoliosis may have deceived the orthopedist; those with rheumatism, headache, other neuralgias and stomach troubles, are among the beneficiaries of removal of infectious foci; but those that pertain to the nervous system are of special interest.

The work done by Dr. Cotton in the State Hospital at Trenton, N. J., commands our attention, and before his critics pass judgment on his work let them first realize what he has attained. With a recovery rate, during the past six months, of ninety per cent. in the group of functional cases, in which class the rate was formerly thirty-seven per cent., one has to make some explanation of this great change in the number of recoveries. Instead of commenting unfavorably on his methods, let his critics improve on them, for until we can show an equal percentage of cures, it does not become us to be too critical of his work, which I believe is the beginning of a new era in psychiatry.

We have been considering diseases that arise from oral infections, which are not necessarily fatal, although many do play an important part in the cause of death, and include discomforting illnesses and life long misery.

We do not expect to emulate St. Mungo, founder of the Cathedral of Glasgow, who reached the age of 185, or H. Jenkins, of Yorkshire, who died at 169, or Thomas Parr, who lived to be 152, but we do believe that seventy is not an unreasonable age to look forward to and when we see many die at an earlier age, believe many of their diseases to have been preventable. It is said that "dead men tell no tales," but their teeth do. A patient, aged forty-six, consulted me one day, complaining of a bad feeling in the head. His teeth were decayed and I advised their removal, which was not done, and the next time I saw him, three months later, he was laying on the floor of his room, dead, a revolver by his side and a bullet in his body.

A woman, aged fifty-five, who was mentally depressed and had harbored infection in her mouth for a long time, could not be prevailed upon to have teeth extracted, and her children did not wish to employ force in having it done. A year later I saw her hanging by the neck, dead.

A man, aged thirty-six, whose oral infection was thought to be the probable source of his mental depression, was in an institution for observation, from which he was sent home with the advice to go to work, but two days later I viewed his remains as they lay in a pond.

I have been making close examination of teeth in cases of sudden death for a comparatively short time, but have seen six suicides, in which the average age was forty-six, and twelve sudden deaths in which the age averaged fifty-one, in all of which there was evidence of infection in the mouth, and in none had all the teeth been extracted.

Let us for a moment consider what is health, and what does it mean to us. It is a prize above all other things; it is what we desire ourselves and even greater is it desired to have it in our homes. It makes a community, a state and a nation strong.

A great responsibility rests upon us, whose advice helps to determine the health of the nation. Therefore, if people without teeth are more healthy than those who have them, preserved by fillings and crowns, let us advocate more false teeth, for dentistry is a failure if it cannot maintain teeth in the mouth which are not a menace to health.

The extraction of teeth, as quite generally practised, is, however, a two edged sword, for in removing carious teeth we may cause more trouble through systemic infection, which may be worse for the patient than the original trouble. Within the past year I have seen death from pulmonary thrombosis, which occurred two weeks after the extraction of six teeth by novocaine. In consultation I have seen a case of most serious illness, closely following heavy extraction under ether, lasting six months; exact pathology undetermined, but related to the lungs. In the practice of a surgeon friend, a young woman, who had just had heavy extraction under ether, became very ill, abscess of the lung developed. She was operated on and died two weeks later.

I have seen other illnesses existing over periods of weeks and months; some of these illnesses arise from inspiring infection when under ether, while others arise from metastasis.

The necessity of removing many teeth being great, it is important that the operation should be so conducted as to eliminate existing infection, and reduce to a minimum the dangers of systemic infection. Time will not allow detailed accounts of beneficial results that have followed the removal of dental foci of disease, some of which are of extreme interest.

Personal experience is a good teacher and I obtained knowledge of the danger of dead teeth in this way. The x ray did not reveal the infection, but following their extraction troubles of long standing disappeared. It having been proved that dead teeth are potential factors in disease, what are we to say to patients who possess such? There is but one thing to say and that is—have them out.

In several articles which have been published, x ray findings have been given to show the relations of teeth to certain diseases, but nothing is said about the standards which govern the röntgenologist when he says that teeth are all right. This might be very misleading as it is common knowledge that infection, following extraction, is demonstrated with a negative x ray report and unerupted third molars are probably always infected, even though not read on the film.

We hear criticism of the relations of teeth to disease in cases cited where extraction was done without benefit, which is not evidence that attempted removal of infection was not justified, but emphasizes the necessity of the surgeon's knowledge and skill in obtaining the best results. We think that the time is not far distant when specialization in dentistry will be more general.

The remarkable resistance which some people possess against the invasion of all diseases is something we would like to be able to give to our patients, and although we may not succeed in so doing, except in a limited degree, we think that a removal of Streptococcus hemolyticus or Streptococcus viridans from the blood stream, with disappearance of the lymphocytosis, would better enable our patients to fight other invaders when they appear.

As a help in the campaign of education let us formulate a method of procedure that all will agree is proper and then use influence to have these methods put into practice in hospitals and public institutions. The plan should include removal of all roots, badly decayed and devitalized teeth, with due regard to surgical cleanliness, but if all cannot agree as to the devitalized tooth, let us begin with old roots and badly decayed teeth. Although this method would be crude, it would focus attention on these things and would probably lead to a proper equipment for study and treatment not unlike that maintained in the State Hospital at Trenton.

The present work done in some of our State institutions along the line of dental hygiene is a farce. How can you expect the indifferent physician to change his attitude so long as his patients, in the hands of specialists, have so little attention given to these infections?

Those who have had repair work done, be they sick or well, should have existing infection removed. In cases of severe illness, where repair work has been done, do not take it for granted that infection is nonexistant, if not apparent, for just as the miller does not see everything that floats by the mill, so the little streptococci sometimes gets by the röntgenologist.

Hippocrates said: "There are really two things, knowledge and opinion, of which the one makes its possessor really to know, the other to be ignorant," so today the physician, who is observing the effects of removal of dental infection, knows that a large number of patients are benefitted by this treatment. Having gained this knowledge by observation, he foresees the larger field for practical application of this knowledge, and a disappearance of many diseases the physician and surgeon are now called upon to treat.

Present Status of the Pulp and Root Canal Problem

By M. L. RHEIN, M.D., D.D.S.,
New York,
Lecturer on Dental Pathology, University of Pennsylvania.

Looking through the writings of some eminent physicians during past centuries we occasionally find a reference to the injurious effect of diseased teeth on health. In 1818 Dr. Benjamin Rush, who was connected with the University of Pennsylvania, was so impressed with the importance of this subject that he made a very valuable contribution in reference thereto. The sporadic efforts of such few physicians of note calling attention to this matter left practically no imprint on medicine, because their observations were of a purely clinical nature, and empirical at that.

While studying medicine in 1879 my attention was directed by my father to the deleterious effect on people of the absorption of pus in the mouths of many patients who came under his observation. From that time my attention has been constantly directed to the efforts being made, not only to prevent such conditions, but to provide the proper means of curing diseased conditions caused by dental focal infections and still preserve the natural teeth so that they will not be a menace to the health of the individual. In 1882 Sir Lawson Tait, the celebrated gynecologist of Birmingham, England, came to the United States at the invitation of Dr. Albert Vander Veer, of Albany. A number of ovariotomies, which he performed at the Albany Hospital, were the first demonstration in this country of present day aseptic surgery. Having the honor of assisting at these operations, I was at once impressed by the beginning of a new era in aseptic surgery, and from that time have modeled the technic of all root canal operations on a similar basis of absolute asepsis.

At this period the recognized dental practice for the prevention of suppuration in root canals was the use of either carbolic acid or creosote. The latter was the one mostly favored and the most foul smelling that could possibly be found was the one that was considered to have the greatest virtue in its ability to disinfect the parts on which it was used. The use of this agent has never been abandoned by a large number of practitioners, and today its odor, which lingers about the office, is sufficient evidence that the practitioner still follows this antiquated procedure.

In the early eighties I started an endeavor to impress both physicians and dentists with the relationship that existed between infections in the dental regions and the general health of the patient. Although I wrote numerous articles on this subject, in which I called attention to the localized pathological dental conditions due to different types of malnutrition and to the various diseases caused by dental focal infection, my observations received but scant attention. It was not until Hunter, of London, aroused the medical world to the damage done by septic dentistry that the medical world as a whole realized the gravity of the situation.

The lack of dental education in the medical curriculum has ever since caused the medical men to blunder about this situation in an empirical manner. In the first place he has failed to grasp the difference between septic conditions in the mouth that are purely symptomatic of different types of malnutrition, the local pathological conditions which are generally known as pyorrhea alveolaris, and dental focal infections which are generally caused by infection of devitalized pulps in teeth. It is this latter condition which has been productive of so many cases of heart lesions, arthritis, etc., and has caused the physician to revolt against the orthodox methods of the dentist in handling pulpless teeth. Clinical demonstrations have proved beyond doubt that frequently unnatural rises in blood pressure, various types of heart lesions, arthritis, nephritis, diabetes, gallstones, ulcers of the stomach, appendicitis, etc., were unquestionably caused by the absorption of the toxins, the result of streptococcal foci nurtured by decomposing pulp tissue.

Although many able dentists have been working steadfastly to maintain a technic of therapy that would leave a pulpless tooth in the jaw in such condition that it ceased to be a menace to general health, they have failed to gain a sufficiently large following. This failure of the mass of dentists to take up scientific root canal therapy is due to a number of causes. Economic pressure has perhaps had the largest influence in preventing the mass of dentists from adopting a scientific root canal technic. This technic involves the removal of every particle of pulp tissue found in the root. It means the eradication of any diseased area in the alveolar structure around the end of the root. It means maintaining the root canal in an absolutely aseptic condition. It means hermetically sealing the end, thus insulating the root canal from the living tissue, so that no microorganisms could gain access to the canal from the surface of which they might obtain sustenance. An operation of this kind requires infinite patience together with absolute sterility of technic, and requires such a vast amount of time for its successful accomplishment that of necessity it has to be subdivided into numerous operations, all of which have to be checked up bacteriologically and by the x ray. The expense of such an operation, on account of the time expended, has unquestionably prevented the mass of the profession from undertaking its study. The delicacy of manipulation and the skill required, to say nothing of the temperament required for such an operation, has precluded absolutely a certain portion of the profession from successfully attempting it. This meant that the general mass of dentists continued in the orthodox method of handling pulpless teeth without regard to the possible damage they were inflicting on their patients.

As the evidence of danger to life itself began to be unfolded in the various professional articles that were published and lectures that were delivered, the conscience of many dentists revolted and there was started what was known as the "one hundred per cent. club," that refused to retain any pulpless teeth in the mouth. This, in turn, was followed by a wave of wholesale extraction of teeth which carried in its wake the loss of countless useful teeth. During the past few years the "one hundred per cent. club" has been steadily losing ground. A more or less concerted activity has started to prevent the wanton destruction of so many useful teeth. While it is true that balanced in the scale of judgment a healthy heart is of infinitely more importance than the retention of a tooth, we must not lose sight of the inordinate value that healthy teeth have in a healthy mouth for the proper maintenance of health. No artificial teeth, however skillfully constructed, are an ideal substitute for the natural organs, although they may serve a very useful purpose.

This revulsion of the feeling of the mass of the profession against wholesale extraction of teeth has unfortunately brought into the limelight of clinical activity the commercial instincts of various dental supply houses. As a result various schemes are attempted by means of which the lure is held out to the dentist of saving pulpless teeth in a manner that will not compel him to devote any such unusual amount of time, energy and skill.

This lure consists in the presentation of different methods of embalming the pulps, or whatever remnants of the pulps may remain in root canals. The object of the vendors is the sale of different types of proprietary remedies disguised under various fanciful names and hidden by different commercial schemes. That is what the public have most to fear from at the present time.

What is the remedy? Dentistry is a specialty of the healing art for the practice of which there is requisite so many different types of skill that it necessarily has become divided into specialties of its own. One of these specialties is especially distinguished by the remarkable benefits it has conferred upon humanity during the past twenty years. Before that time the correction of malformation of the mouth, irregularities of the teeth, and deformities of the jaw was practised more or less by the general practitioner. The result of such practice on the whole was more or less disheartening. When, however, orthodontia became a well marked and distinctive specialty practised by men especially educated therefor, to the exclusion of every other type of dentistry, it succeeded in producing a result that was nothing short of marvelous when compared with the conditions prevailing thirty years ago. The able orthodontist of today is one of the greatest apostles of successfully practised preventive medicine.

Every investigating dentist and physician can find the absolute proof that a certain percentage of pulpless teeth can be treated in such a manner that when the operation is completed they cannot be in any way regarded as a menace to the health of the individual. The only way in which the public as a whole will obtain the benefit of such treatment will be when the treatment of pulpless teeth becomes as much of a specialty in dentistry as orthodontia is at the present date. When the dentist who feels a desire to follow this particular field of practice devotes a sufficient amount of time to a course of instruction in this specialty, and then devotes himself entirely to the treatment of such conditions as would come under such a specialty, the public will be materially benefited.

Although our dental schools are working diligently to improve the situation, it cannot be denied that the great majority of dentists are lacking in a proper understanding of general pathology. They look upon their calling mainly as one of craftsmanship and feel that any unsuccessful operation reflects on their ability. Every surgeon realizes that every operation performed with all possible skill is attended by a certain percentage of failure for which he cannot be held accountable. Not so with this class of dentists; fearlessly they undertake pulp operations and often having operated with great skill meet with failure. Like the general surgeon they should frankly admit the failure of the operation. Unfortunately they have not been educated as physicians but as artisans, and fear that the admission of failure will not only injure their professional reputation but will possibly make them defendants in various malpractice suits.

It must be understood that a large percentage of pulp cases may result in failure and yet not leave a trace of discomfort. Generally, there is no exterior evidence of failure. Only the bacteriological laboratory and the x ray will disclose the fact that the focal infection still exists. Fortunate is the patient whose dentist has the moral courage to inform him frankly of failure, and that the tooth must be removed and the diseased surrounding structures extirpated.

The percentage of failure in pulp operations varies greatly, dependent on certain conditions. The removal of a pulp where no infection exists should be successful in about ninety-five per cent. of cases. Where the infection has not attacked the alveolar structure, but remains in the root canal, this percentage is only slightly decreased. Where destruction of the alveolar structure has begun, but the investing pericemental lining membrane of the root remains intact and no prior operation has been performed, the percentage should be well above eighty.

Wherever a prior operation has been performed it becomes very difficult to make an estimate of the possible percentage of success. Whenever the cementum of the root has been attacked and destruction of the cementum begun, the prognosis is very bad. Few men of ability will operate under such conditions. Nevertheless, in such cases operations have been successful.

We have learned to base our diagnosis of foci of dental infection in a large measure on the destruction of alveolar structure around the end of the root. Like the remainder of the body, the destroyed alveolar structure is regenerated when the pathogenic tissues have disappeared. To feel confident in assuming that the operation was successful the x ray within the year should disclose regeneration of previously destroyed alveolar structure.

Vincent's Infection of the Mouth*

By ISADOR HIRSCHFELD, D.D.S.,
New York.

In recent years Vincent's infection has been written up extensively and profusely. Its frequent occurrence during the world war among soldiers and sailors, at home and abroad, and even among civilians, stimulated the dental and medical professions to great activity in its study and the recording of its diagnosis, etiology, and treatment. Assuming that the subject is a more or less familiar one, I shall give only a brief review of it as a whole and discuss more fully those points which I consider either have not been brought out hitherto or have not been sufficiently emphasized.

The term Vincent's infection was recommended at the last meeting of the National Dental Association by the Committee on Nomenclature, and refers to the disease of the mouth supposedly caused by Vincent's fusiform bacillus and spirillum appearing jointly either in symbiosis or as variations in form of the same organism. Their true relationship has not yet been definitely established. Until recently this disease has been variously known as ulceromembranous gingivitis (Grieves), phagedenic gingivitis, Vincent's infection of the gingivæ, acute ulcerative gingivitis (Gilmer), phagedenic pericementitis, trench mouth, Vincent mouth, Vincent's angina, ulcerative gingivostomatitis due to Vincent bacillus, etc. At the present time we commonly designate the infection when in the throat as Vincent's angina, and when in the mouth as Vincent's infection.

Vincent's infection is both infectious and highly contagious. It may occur either in pure form or mixed with other acute or chronic infections of the mouth. Because of this latter fact, a detailed knowledge of all the clinical symptoms of Vincent infection is indispensable to the stomatologist. It is most prevalent in individuals between the ages of twenty and forty (occasionally occurring before twenty but rarely after forty) and is found more often in men than in women. It is not apt to invade a mouth in which excellent hygiene is maintained.

ETIOLOGY.

In addition to the virulence of the Vincent microorganisms, the other factors required for the establishment of the infection seem to be a coincidental general lowered resistance plus a suitable local soil in which these microbes may gain a foothold. Close observation in practically all cases of Vincent's infection will disclose the fact that, primarily, these organisms attack and spread from those areas of the soft tissues in which circulation has been previously impaired by mechanical, chemical, or bacterial trauma. It will also be found that these foci are so situated that the bacteria are protected from the cleansing action of mastication and from the usual haphazard use of the toothbrush. The following may be such locations: The flap of gingiva partly covering the lower third molar; the acute angle formed by a sharply inclined drifting tooth; the interproximal gingivæ where teeth overlap and form emphasized embrasures; buccal gingival margins of second and third upper molars, the lingual gingival margins of second and third lower molars, and on the mucous membrane of the cheeks or tongue or floor of the mouth immediately adjacent to these points; near the overhanging margins of faulty dental restorations; the gingivæ covering teeth which are either in marked traumatic occlusion or in infraocclusion; palatal margins of the anteriors where the gingivæ are constantly inflamed by mouth breathing or by excessive smoking, especially of cigarettes; and in preexisting interproximal pyorrheal pockets.

CLINICAL SYMPTOMS.

The following are the outstanding clinical symptoms: Ulceration and sloughing of the marginal gingivæ—especially interproximally. The necrotic layer, yellowish white or grayish white, may be easily wiped off from its base or red line of demarcation which is highly inflamed. Immediately below this line the gingiva may appear fairly healthy. This red base is extremely sensitive, painful, and bleeds freely on the slightest provocation. The ulceration may occur on the mucous membrane of any other part of the mouth and throat in the form of yellowish white or grayish white patches with well defined inflammatory margins. Usually the bacteria invade the gingivæ in various parts of the mouth at the same time, but they may confine themselves to one side of the mouth, either right or left, involving the upper and lower jaws on that side. The fetid breath almost always present is distinctly characteristic and easily differentiated from other types. These symptoms usually come on suddenly and are often accompanied by a metallic taste, increased salivation, swelling of submaxillary lymphatic glands, also malaise, rise in temperature, and mental depression. (In reference to the last named symptom, it may be interesting to note that within one week, each of two women patients suffering from a Vincent infection indicated her state of mind in exactly the same words, "If it were not for my small children, I would jump into the river." In both cases, the point of view was changed at the second visit.)

---

*Read before the Hudson County Dental Society, Jersey City, N. J., March 2, 1923.

Although one would logically expect to find that the intensity of the systemic symptoms is proportionate to the extent of the local symptoms, the contrary is sometimes true. Instances have been observed in which fairly advanced cases produced comparatively minor systemic reactions while those with mild local symptoms exhibited decided systemic derangement. As a general rule most of the above named symptoms are found in the mouth presenting the typical, acute Vincent's infection, but there are cases which present only a few, some of the symptoms considered cardinal even being absent. This fact should be emphasized, as there seems to be a general impression that all or most of the symptoms must be present in order to make a positive diagnosis of a Vincent infection. In fact I know of some instances in which a wrong diagnosis was made by dental and medical practitioners simply because they were misled by the absence of some of the symptoms.

The bacterial findings in the average case are strongly positive, i. e., a great number of fusiform bacilli and spirilla are found. However, the following interesting variations have been observed: the first smear taken in an incipient case showed a heavy bacterial count, while in a similar case the first smear yielded no Vincent finding—though typical findings were obtained several days later. On the other hand, in a fairly advanced case the primary smear was negative.

Another point in diagnosis which should be emphasized at this time is the fact that positive bacterial findings are not in themselves conclusive. Mouths showing no symptoms of an acute Vincent infection, either subjective or objective, may often show the presence of Vincent microorganisms in large numbers. A table of smears which I took from seventy-five mouths, chosen at random from among my patients, having no clinical manifestations of Vincent infection, shows the following findings:

No Vincent bacilli and spirilla present	24
Spirilla only	12
Bacilli only	1
Moderate number of Vincent bacilli and spirilla	32
Large number of Vincent bacilli and spirilla	6
Total	75

Therefore, the presence of a large number of Vincent bacilli and spirilla does not by itself denote an acute disease, though it may indicate a possible mild, chronic infection. It may, however, be a predisposing factor of disease and the bacteria should be eliminated or at least reduced in number as a preventive measure.

It may be in place, under clinical symptoms, to mention the following variations which I have observed in several instances:

1. The bright red line of demarcation, instead of terminating abruptly, continues into the alveolar gingiva towards the areolar mucosa, with a gradually lessening intensity until it merges with the normal pink.

2. The gingival margins were intact and not necrotic, but the entire affected gum was cyanotic in appearance, slightly bloated, and extremely painful to touch. The condition responded to Vincent treatment with a rapidity characteristic of a Vincent infection. The bloated gingivæ collapsed immediately, assuming a wrinkled appearance, and the pain was eliminated almost completely. Then the gingivæ rapidly resumed their normal color, form, and consistency, leaving no trace of the bluish color.

3. When the margin of a flap of gum overlying a preexisting pyorrheal pocket is affected by an acute Vincent infection, the red line of demarcation is very often not discernible—the necrotic area is in apparent contiguity with the bluish gingival flap.

DIFFERENTIAL DIAGNOSIS.

Vincent infections in which only a few of the typical symptoms are present may be mistaken for other lesions having similar characteristics. As I have found that a bacterial finding, either positive or negative, is not an absolute guide in diagnosing a Vincent infection, I feel that a clinical differential diagnosis is of vital importance.

Among the lesions most likely to be diagnosed as Vincent infections, or vice versa, are:

1. Pyorrhea alveolaris (suppurative periodontoclasia)
2. Mercurial stomatitis.
3. Aphthous stomatitis.
4. Mechanical trauma.
5. Staphylococcus infection of the mouth.
6. Lesions produced by drugs.
7. Tuberculosis.
8. Syphilis.
9. Pemphigus.
10. Diphtheritic sore throat.
11. Herpetic lesion.

1. *Pyorrhea alveolaris.*—In pyorrhea alveolaris macroscopic pus is usually disclosed upon pressure on the gingiva, with no pain except when complicated by an acute infection, such as a parietal or gingival abscess. It does not present any necrotic gingival margin and the loss of peridental tissues may be on any or all sides of the teeth. In the pure type of Vincent infection there is no macroscopic pus in evidence and the gingivæ are very painful to the touch—in fact, mastication on the affected parts becomes impossible. The marginal gingiva is necrotic and the destruction is found particularly between the teeth.

2. *Mercurial stomatitis.*—Ulceration has a dark grayish blue appearance and there is no special tendency towards interproximal ulceration as in the Vincent infection. The devastating process occurs on the gum margins all around the teeth equally and the inflammation may extend down to the areolar mucosa, whereas in Vincent's infection it usually does not extend much beyond the bright red line of demarcation. Marked necrosis of the bone occurs more often and loosening of the teeth is more likely to occur in mercurial stomatitis than in the Vincent infection. Besides, salivation may be more marked and the tongue often swollen. History of the condition indicates the use of mercury in some form either by mouth or intramuscularly.

3. *Aphthous stomatitis.*—This condition is most likely to occur away from the gingivæ proper. The necrotic material is very tenacious and lighter in color than that of a Vincent infection. There is

likely to be a history of indigestion and a complaint of socalled heartburn. In contrast to this, Vincent lesions occur most often on the marginal gingivæ and the necrotic material can be detached very easily (wiped off).

4. *Mechanical trauma.*—The careless use of a tooth brush, food impaction, artificial dentures, bridges, etc., may cause trauma. The condition simulates aphthous stomatitis in appearance and painfulness.

5. *Staphylococcus infections.*—Infections of the oral mucosa with the staphylococcus, as I have observed them, are small ulcers resembling aphthous sores in color and painfulness, are sometimes round, but generally oval, and are a little larger than a pin head. They occur mostly as groups of individual lesions but at times coalesce. They appear on the palate, gingivæ, and on the inner side and the vermilion of the lips. They are not especially inclined to affect the gingival margins or interdental papillæ. They resist treatment very stubbornly and when they appear with a Vincent infection, they respond more slowly than the latter lesions.

6. *Lesions produced by drugs.*—Luminal used in nervous conditions as a sedative may cause lesions in the mouth simulating those of the Vincent infection. Phenolphthalein, ex-lax, phenol-lax, and certain coaltar products may act in the same way. The eruption is that of a bullous type and the small bullæ may be seen in the early stage. The ulceration is more inflammatory. There is usually a complete history of the ingestion of drugs in nearly all cases.

7. *Tuberculosis.*—In neglected and aggravated cases, ulcerations of the checks, gums, or tongue may occur. They are characterized by ragged edges, with a dirty gray pultaceous base, studded with small tubercles, which show tubercle bacilli on microscopic examination.

8. *Syphilis.*—The mucous patches of syphilis are more or less sharply demarcated, are of a grayish white color, on a noninflammatory base and are not very painful. There is usually a history of a recent infection or the presence of a primary lesion with other secondary manifestations of the disease, as well as a positive Wassermann test.

9. *Pemphigus.*—Cases of pemphigus, in their early stages, where the lesions of the mouth antedate those of the body by months, have been diagnosed as Vincent infections. When the bullæ characteristic of pemphigus are undisturbed, Vincent infection is easily ruled out, but where they have collapsed, the bases may resemble Vincent ulcers. However, strands of the deflated bullæ are apt to be left around the margin of the base. There is also no probability of marginal and interproximal destruction of the gingivæ.

10. *Diphtheria.*—A pseudomembranous exudate in the throat is of a dirty gray color, is strictly adherent, and rarely appears around the teeth. There are constitutional symptoms and the positive findings of the Klebs-Loeffler bacillus in diphtheria.

11. *Herpetic lesions.*—These appear as distinct isolated vesicles at the beginning. The eruption usually improves after a few days even without treatment and the microscopical finding is negative.

The question, "What drugs do you employ in the treatment of Vincent's infection?" sounds about the same to the clinician as the one heard so frequently, "What scalers do you employ in the treatment of pyorrhea (suppurative periodontoclasia)?" Both questions often indicate the mistaken idea that drugs and scalers are the means of curing these diseases. The fact really is that they are only valuable aids to other almost equally important factors in a successful treatment. Medication in a Vincent infection is directed against the pathological microorganisms only and should be accompanied by painstaking efforts to restore the immunity of the mouth and to improve the general resistance of the patient.

Treatment is therefore carried out by me as follows: At the first sitting all necrotic material is removed as lightly as possible, either by picking it off with cotton pliers or, preferably, by wiping it off with a tapering swab of cotton, on the end of a toothpick, saturated with a ten per cent. solution of neosalvarsan in glycerine. The patient is asked to obtain, immediately upon leaving the office, an original one pound package of sodium perborate with which to make a solution—one teaspoonful to three quarters of a glass of tepid water—to be used every half hour until otherwise instructed, rinsing the mouth thoroughly with the entire contents each time, and forcing it through between the teeth. Where systemic disturbances are manifest, the patient is advised to take a saline cathartic at once, to use a light diet, to rest as much as possible, and if necessary to stay home from work. Superficial scaling of the teeth, though sometimes advantageous at this sitting, is not often undertaken at this time for the following reasons: the patient is usually physically unfit for a long session; the first visit is apt to be an emergency treatment and therefore necessarily short; and also because the odor is too obnoxious to allow the operator to work at close range for the additional time required. Notwithstanding the unhygienic condition of the mouth, tooth brushing is not encouraged at this time and the patient is asked instead to use gently a swab of cotton soaked in the perborate solution. Smoking is temporarily prohibited.

Almost without exception, the patient returns the next day entirely changed in spirit, alert, and highly appreciative of the sudden marked improvement. He has had a peaceful night's sleep and the systemic symptoms may have disappeared entirely. The ulcerous conglomerate, if developed afresh, is greatly diminished in quantity, and the pain and sensitiveness in the soft tissues are reduced in proportion. At this, the second visit, the operator usually does his superficial scaling and removes all marked traumatic and unsanitary conditions. Neosalvarsan is again used and daily thereafter, until several days after the complete disappearance of the necrotic lesions. When the acute condition seems to have subsided, further scaling is undertaken. Tooth brush instruction is then given the patient who must be made to understand the great importance of thorough brushing, particularly in the interdental spaces. Use of the mouth wash is continued for approximately two months in conjunction with the tooth brush dipped in it, about twice daily, as a precautionary measure against reinfection, and the patient is requested to call fairly often for inspection during this period.

Above all, immediate and intensive treatment is imperative because of the very rapid progress which characterizes this infection, so as to prevent either a fatal termination or such extensive destruction of periodental tissues as to require extraction of the teeth. To insure best and earliest results, treatment by the operator and cooperation by the patient must be carried out from beginning to end with relentless precision. Otherwise, progress is retarded and permanent loss of the investing tissues increased, to the patient's disadvantage.

All surgical operations, such as tooth extractions, should be postponed until after the complete elimination of infection, in order to avoid serious effects.

Vincent infection is generally spoken of, written about, and thought of, as an acute infection. It is one of the purposes of this paper to call attention to the fact that the activities of the Vincent microorganisms may produce acute, subacute or chronic conditions of the gingivæ, and I have a strong suspicion that these organisms may act similarly in the throat, using the dental arch perhaps as a base for their activities.

The subacute condition may be the result of incomplete treatment of an acute infection or it may never have been acute at any time. It may have many of the features of the acute condition but is not so distressing. It may flare up and disappear after a few days without any effort at treatment, only to reappear in the same way several weeks or months later, the balancing factor being, evidently, either the patient's physical condition or the virulence of the microorganisms. It may be accompanied at times by a slight rise in temperature and a mild malaise, and may also present a slight tendency towards a necrotic margin. On the other hand, there may be no macroscopic necrotic tissue in evidence at any time, yet the loss of tissue, especially interproximal, and the red gingival margin simulate the characteristic appearance of the acute infection minus the necrotic border. In some cases the outstanding feature which makes the patient aware something is wrong, is the easily produced hemorrhage.

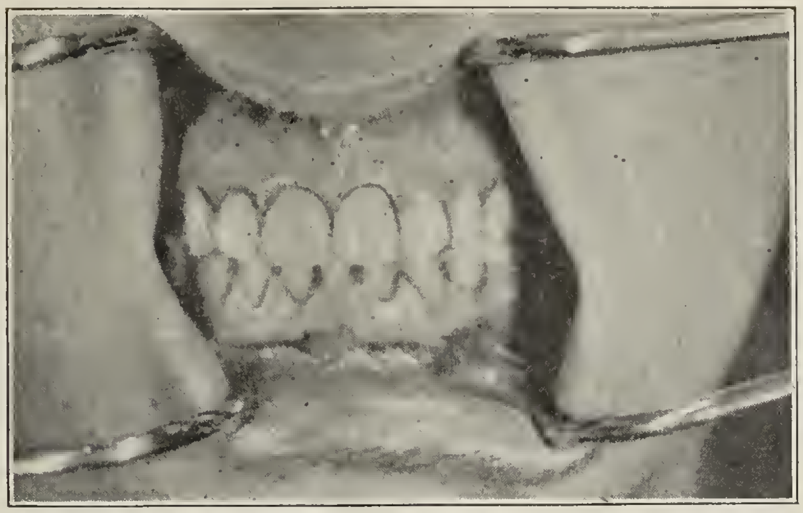

Fig. 1.—Normal gingivæ. The interproximal papillæ reach down to the contact points of the teeth.

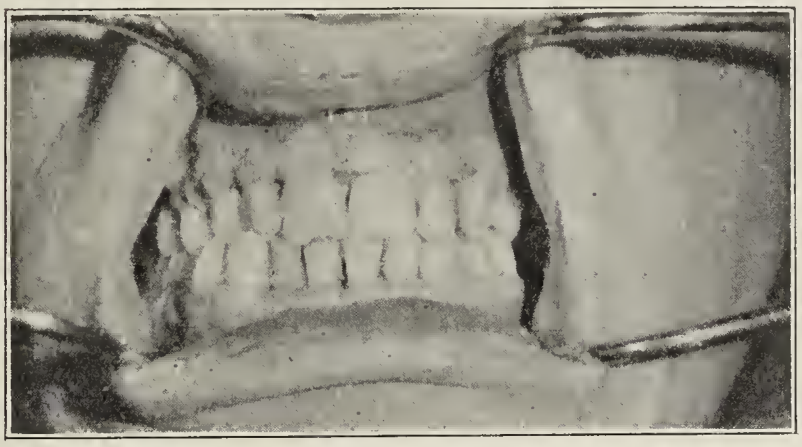

Fig. 2.—Destruction of interproximal papillæ in a case of Vincent's infection. This photograph was taken at the second visit. The only necrotic tissue appearing this time was at the point of the central papilla.

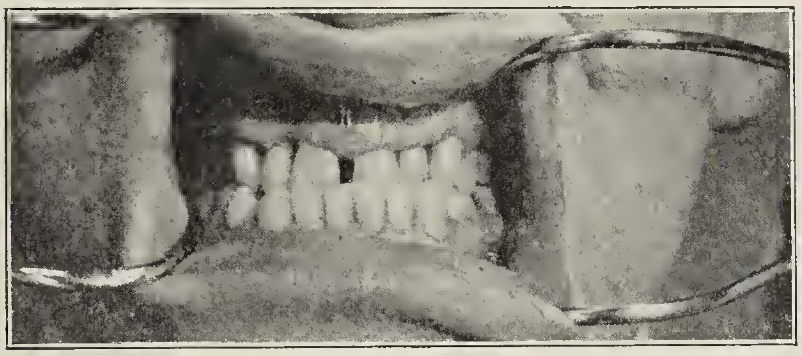

Fig. 3.—Typical condition of the gingivæ in the wake of a fairly advanced case of Vincent's infection.

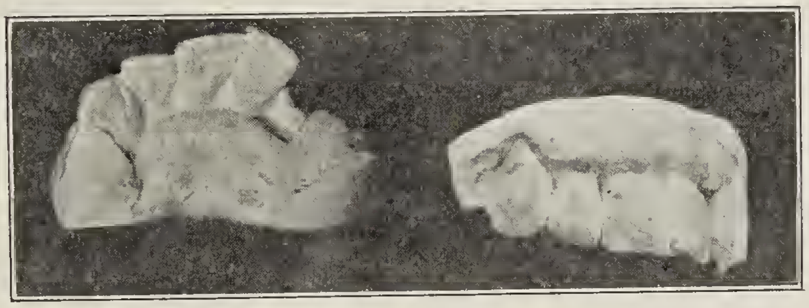

Fig. 4.—Models showing the extreme loss of supporting structures in an advanced case of Vincent's infection.

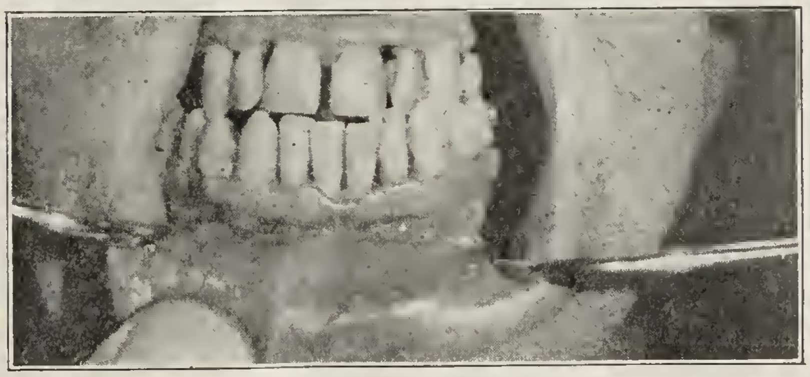

Fig. 5.—Showing appearance of marginal gingivæ in Case II.

Treatment of the subacute type is the same as for the acute and with the same intensity. The following two cases represent this type:

Case I.—Male, aged twenty-four, merchant, came to me for treatment about six months ago with a mild Vincent infection in which there was a slight sloughing of interproximal papillæ and Vincent finding was positive. He was in barracks during the war and since then intermittently his gingivæ were sensitive and bled easily and he suffered from high temperature and malaise. He had his teeth cleaned a year ago, after which the gums were sore for an entire month and sore intermittently thereafter until two weeks prior to his first visit. Response to Vincent treatment was prompt and patient has been feeling well since that time.

Case II. — Physician, aged about thirty, had been in active service in the war. While in the trenches he had neglected mouth hygiene and the gingivæ became uncomfortably sore toward the end of his stay there. Without any special treatment this condition disappeared but had since then reoccurred intermittently, accompanied each time by marked malaise, a noticeable rise in temperature, and extreme fatigue at the end of a day's work. When he came for treatment several months ago, the marginal gingivæ presented the appearance of an acute Vincent infection minus the necrotic tissue but with marked loss of interproximal papillæ. Other Vincent symptoms were also present. In this case the first smear taken was negative, the second one, taken the next day, was slightly positive. After the discontinuance of toothbrushing for two days, a third smear showed a positive Vincent infection. Response to Vincent treatment was prompt.

The following cases are interesting examples of some of the points discussed:

CASE III.—Female, married, aged twenty-four, in an automobile accident, had broken her upper left central and lateral incisors and had sustained other contusions about the face. She was confined to bed as a result of the shock and had considerable rise in temperature for about a week. Salivation became very marked and all the now loosened upper anterior teeth and their surrounding soft tissues became very painful. Fluoroscopic examinations, together with these symptoms, led the attending physician to diagnose the case as a fractured maxilla.

The patient was at this time referred to me for consultation and treatment. She was so weak that she was hardly able to walk and her extreme pallor indicated a very sick condition. The painful condition in her mouth rendered hygienic care impossible and it was consequently in a very unsanitary state. Radiographic findings this time revealed no fracture. The cemental and alveolar gingivæ, labially, showed ulcers of apparently mixed infection. These ulcers were also to be found on the vermillion of the lips and they were especially painful where the lips were chapped. Some of these ulcers were isolated while others were fused. Marginal gingivæ and interproximal papillæ showed typical Vincent infection around the entire mouth, but the destruction was not deep. The breath was extremely fetid. Bacteriological examination showed many fusiform bacilli and myriads of spirilla, also a moderate number of staphylococci. The Vincent symptoms yielded readily to treatment, but the other ulcers disappeared slowly.

CASE IV.—Male, automobile mechanic, aged twenty-seven, when presented at the clinic had all the characteristic symptoms, both subjective and objective, of a fully established Vincent infection extending over the upper and lower anterior teeth and over those of the right side, while the left side, distal to the canines, was apparently not infected. Bacterial findings were positive. Patient responded to treatment rapidly and at the end of ten days his mouth appeared so well that he was told to reduce the intensive home treatment and to report a month later unless he should feel discomfort in the meantime. He came back within one week and this time the left side of the mouth was infected while the right side seemed to be well. Although the patient was placed under the same treatment as before and directions were followed out by him with the same precision, the infection this time continued to spread until the entire mouth was invaded, including the part that had previously been cured. Now, what seems to have occurred was that through enthusiastic catering to the diseased area, the hygiene of the remaining parts of the mouth had been neglected and the Vincent organisms allowed to flourish there until an inopportune lowered general resistance invited infection and also a severe cold. The patient admitted that he had neglected to take the usual care of the parts not diseased because he concentrated on the infected region. The cold started several days prior to the new infection, and it is interesting to note that as the severity of the cold subsided, the pathological symptoms in the mouth ran a parallel course. The contrast between the extremely rapid response to treatment during the first infection and the stubbornness of the second would seem to be due to the lowered resistance of the patient. It seems advisable, therefore, that coincident with local treatment, the general condition should be toned up.

Prognosis varies according to the stage at which proper treatment is instituted, the general health of the patient, and the extent of cooperation. Although a mortality is occasionally reported, this infection yields readily, on the whole, to proper treatment. Where destruction of interdental papillæ is mild, the slight concavities found in the wake of the destruction eventually become convexities, thus simulating the original papillæ except that they are slightly shorter. They retain their function of protecting the interproximal surfaces from decay. Where the papillæ have been destroyed to a greater extent, and with them the alveolar crest, we may expect a filling in of the soft tissue, to the rim of the pocket thus formed. This leaves the cementoenamel exposed to the action of acids and bacteria, and for a time to thermal shock. This condition, though not esthetic, is usually bearable, providing the patient learns to use the interproximal method of tooth brushing and so prevent sensitiveness, caries, and a possible pyorrheal infection. An interesting process of regeneration does occasionally occur, however, through proper postoperative treatment, i. e., new tissue grows up from the bottom of the pocket, and filling the space, grows beyond the rim of the pocket to such an extent that it eventually becomes a fair substitute for the original papillæ.

Where the interproximal tissues have been destroyed to an extreme extent, permanent comfort and health are very often restored only by extraction of the teeth. In such instances, if only two teeth next to each other are involved, in any area, extraction of one may save the other. This condition is likely to be found where deep pyorrheal pockets had existed prior to the acute infection. Buccal, labial, and lingual gingivæ usually regenerate very slightly, but they have a tendency to lose their jagged edges and return to the graceful curve of the normal margin. Where deep destruction of the alveolar mucosa (the mucous tissue overlying the ridge formed after tooth extraction) occurs adjacent to a tooth, remarkable regeneration may take place.

I wish to express my grateful appreciation to Dr. Isadore Rosen, assistant professor of dermatology and syphilology, Columbia University, for his kind assistance with the differential diagnosis, and to Dr. T. S. Schlauch, pathologist to the New York Throat, Nose and Lung Hospital, for his examination of the slides upon which the table was based.

Two additional cases will be included in the author's reprints.

Oral Infection by Vincent's Organisms

By PAUL R. STILLMAN, D.D.S., F.A.C.D.,
and JOHN OPPIE McCALL, A.B., D.D.S., F.A.A.P.,
New York,
Instructors in Periodontia, Advanced Courses in Dentistry, Columbia University.

Vincent's angina is an infection of the throat whose nature and etiology have long been known to the medical profession. The appearance in the mouth of the causative organisms of this disease has also been known for some time. Previous to the world war, infection of the oral tissues by the spirochete and fusiform bacillus of Vincent was comparatively rare. The result was that it received but little attention from either dentist or physician. When so occurring, this disease was labeled pyorrhea, and thereby grouped with several other types of periodontal diseases, to which this name was equally inapplicable. The name phagedenic gingivitis (1) has been applied to this disease because of the rapidly spreading ulceration which is one of its characteristics.

When it was recognized that this disease constituted a distinct type of oral infection, the identification of the causative organisms was made. Their characteristics, as a symbiotic, anaerobic group, were soon established. Although attention was called to this by several dental writers, notably Vaughan (2), Hinman (3) and Grieves (4), the essential nature of this disease remained an unknown quantity to dental practitioners in general until the infection reached epidemic proportions during the world war. Its ravages were not confined to the army and navy but were fairly widespread in the civilian population, especially in the large cities.

The disease is characterized in the typical case by sudden onset, the attack being that of a painful inflammation localized along the margin of the gingival tissues and involving especially the gingival tissue between the teeth. The inflammation is of so violent a character as quickly to cause an ulceration of the border of the gingiva, characterized by the formation of a greyish white slough. In the neglected mouth, or in one presenting evidence of a previously existing chronic disease of the gingival tissues, extension of this area of ulceration may take place with surprising rapidity. The slough may extend rootwise over the buccal or lingual gingivæ, and may thus by extension involve the mucosa of the cheek or the floor of the mouth. Seldom, if ever, does an ulcer appear in these locations as the initial point of infection. The greyish white slough, which consists chiefly of necrotic epithelium, may often be removed with an instrument. Upon removal, a bright red hemorrhagic surface of granulation tissue is exposed, which in the absence of treatment breaks down quickly and forms another necrotic slough.

Due to the rapidity of this process, the bloodvessels early become involved, resulting in hemorrhages, both spontaneous and induced. These hemorrhages may take place during the night and when so occurring are a definite diagnostic sign of the disease.

The breath acquires a characteristic foul odor, which is frequently recognizable even in the absence of acute symptoms. Sleeplessness and loss of appetite are common, as is also the occurrence of some degree of fever. There is a decided malaise, although the patient is seldom confined to the house or even incapacitated for work. The violent nature of the attack induces an apprehension as to the nature and outcome of the disease.

It is most common in those whose mouths are neglected. Cigarette smokers seem particularly susceptible. Syphilitics are likewise extremely susceptible, although the infection may occur without association with this disease. This fact is mentioned because so many patients manifesting Vincent's infection have been improperly suspected of having specific disease. It is, nevertheless, true that antisyphilitic medication, especially arsphenamine, is effective in its treatment.

During the acute stages of the attack and because of the alarm which it causes, the family physician is frequently called before the dentist is consulted. Also, this infection not uncommonly occurs in the mouth of a patient suffering from some confining disease. The physician must, therefore, be able to make a diagnosis and in many cases give such treatment as will serve to ameliorate the symptoms. The case should, however, be referred as early as is feasible to the dentist. The reason for this is, that many of the predisposing causes are of a purely dental character. Therefore complete resolution is not to be looked for except through treatment for which the dentist is especially trained.

Since the exciting cause is an infection by bacteria, it follows that any efficient nonirritating antiseptic will give beneficial results. Emphasis is to be laid on freedom from irritation quite as much as on the efficiency of the drug. For instance, escharotics, including tincture of iodine used alone, are positively contraindicated. Astringents also are of but little value. On the contrary, it has been found that a combination—an aqueous solution of iodine, such as Churchill's, in combination with twenty per cent. silver nitrate—is particularly effective. The iodine solution is applied by any convenient means, as, for instance, a pledget of cotton, followed immediately on the wet iodine by a similar application of the silver nitrate. The result of this application is to produce a precipitate of silver iodide upon the tissues, the chemical interaction eliminating the irritating effects of each drug. This application may be repeated at intervals of two days, if found necessary, but should not be applied over a long period of time. The application should be made directly upon the ulcer.

Sodium perborate is prescribed as a mouth wash, the directions being to dissolve a teaspoonful in half a glass of water as hot as the patient can comfortably bear it. This is used at intervals of half an hour, or less often, according to the severity of the attack.

The sodium perborate must be fresh in order to be effective. Its efficiency lies in its power to liberate oxygen, since the Vincent's organisms are anaerobic in character. It has a greater value than peroxide of hydrogen as it liberates its oxygen more slowly. It is mildly alkaline in reaction and is therefore devoid of the irritating qualities found in the usual peroxide solution. Peroxide of hydrogen diluted with a mild alkaline solution may, however, be used if fresh sodium perborate cannot be obtained.

Many other drugs have been advocated for the treatment of this condition, such as chromic acid, a solution of arsphenamine and glycerine. The agents here recommended, however, have proved particularly satisfactory by reason of the rapidity with which they check the infection and the speedy relief from pain afforded the patient.

Among the underlying causes of this infection are the accumulation of calculus and other concretions upon the tooth surface; irritation of the gingivæ by tobacco smoke; the presence of rough fillings, edges of crowns, etc. Another important cause is the influence of an irregular application of stress to certain teeth in the act of mastication. This inharmonious action of the teeth when in function has been called traumatic occlusion (5). It has been called to the attention of the dental profession only during the last few years as a causative factor in socalled pyorrhea. It has also been found that this condition is a frequent factor predisposing to Vincent's infection.

Subsequent to the prescribed medication, the factors just enumerated should receive attention. The deposits are to be removed and the surfaces of the teeth polished. Traumatic occlusion, if present, is to be corrected.

The toothbrush which is the usual means of maintaining sanitation is contraindicated in the acute stage of the disease, since it causes laceration and irritation of the ulcerating gingival tissues. The patient may use instead a swab of cotton dipped in sodium perborate solution. This should, however, be supplemented by frequent cleansing by the dentist.

This disease may have a fatal termination in the absence of treatment. This seldom occurs, however, except in patients previously suffering from extreme debilitation, exposure to the elements, etc. Usually the natural resistance of the patient is sufficient to bring about an attenuation of the infecting organisms even in the absence of treatment, with the result that the infection becomes chronic and may lose nearly all its cardinal symptoms. Diagnosis may, however, be made through the identification of the spirochete and fusiform bacillus in the smear.

Intense as is the virulence of the acute attack, cases of Vincent's infection show a surprisingly rapid recovery when correct dental treatment is instituted. These same cases may, however, run a long course of acute and subacute symptoms in the hands of the inexperienced practitioner. The prognosis for this condition is nearly always favorable when a correct diagnosis has been made and proper treatment given.

Evolutionary Development of Reconstructive Dentistry*

By M. DIAMOND, D. D. S.,

New York,

I am an American, but I wish to speak to you, not as an American dentist to English dentists, but as a member of the dental profession to my fellow members. Art and science know no limitations of a geographical or national character; and dentistry which is a combination of both art and science must refuse to recognize such limitations. It is no longer remembered particularly that Shakespeare was English in an appreciation of his art all over the world, or that Rembrandt was Dutch; nor does the fact that Einstein is German prevent the award of a great universal tribute to a living individual for his scientific discoveries; and when administering general anesthesia for medical or dental purposes, we do not call to mind that Wells discovered its application and that he was an American.

That a nationalistic spirit does exist in dentistry we can not deny. We think and speak specifically of American dentistry as something quite apart and different from English dentistry. And yet we all have the same duty to perform, the same service to render, the same objective before us—to minister to the care and health of diseased tissues in the mouths of humans and to reconstruct destroyed parts as nearly as possible to meet with all the normal, anatomical and physiological demands placed upon us by Nature. The problems confronting the dental profession are too important to be interfered with by any nationalistic or tribal spirit, and an influence so retrogressive must be ignored.

Perhaps with the exception of feminism, dentistry is the youngest movement in existence. It received its first impetus from Pierre Fauchard early in the eighteenth century, a little less than two hundred years ago. I do not affirm that modern dentistry began with him, but rather that the dentistry movement began with him. Fauchard was a keen observer, and made ingenious attempts to contrive reconstructive methods, but unfortunately the backbone of reconstructive dentistry did not exist at the time. Fauchard's data were strengthened in the half century that followed by Robert Bunon, of France, Thomas Berdmore, of England, and by Philip Pfaff, of Germany, who, with the introduction of plaster of Paris, gave the first impetus to reconstructive dentistry. Berdmore gave the first impetus to dentistry in England, and one of his disciples, Woofendale, was, in 1768, the first recorded dentist in America. The scene of activity remained in England through John Hunter, who as a general surgeon contributed to the modern conception of both tooth anatomy and the physiology and pathology of all structures. His experimentations with plantations of teeth are well remembered. Indeed, he served to establish a scientific attitude that has been rigorously increasing in intensity.

---

*Lecture delivered before the Royal Society of Medicine, London, July 25, 1921. A clinical demonstration followed the lecture.

And now the scene shifts once more to France, where toward the end of the eighteenth century mineral porcelain was conceived by Duchateau, a chemist, because of his sensitive reaction to the organic instability of the ivory substance of his denture and later applied by de Chemat. The enormity of this find is easily appreciated. The cornerstone of reconstructive dentistry was laid. This marked the beginning of a new century and a new era.

From this point I am constrained to refrain (with the probable exception of occasional references) from the consideration of the development of orthodontia, and of the histology, anatomy and pathology of teeth and the other component tissues of the buccal cavity. I shall also refrain from a consideration of the other branches of dental science, although the need of a thorough knowledge of all of them is imperative, even though one confine himself to the practical application of only one. But having prepared the soil from which reconstructive dentistry springs, it is meet that we now concern ourselves primarily with its growth.

We find, on summarizing the status of reconstructive dentistry at the beginning of the nineteenth century, that while it had received considerable impetus during the preceding century, it was nevertheless in a state of empiricism. The situation, however, began rapidly to take on new proportions. During the first half of the new century much was done to develop the industry of mineral porcelain, in texture, shading and anchorage. Today it is interesting to see some specimens fused by Asch and Sons about ninety years ago. They had evidently found, very early in their career, the secret for producing the most compact porcelain and the simplest and most effective system of anchorage. During this period porcelain teeth were used on metal bases adapted to plaster impressions, and with clasps adapted against naked teeth, served to present an appliance reconstructing any number of teeth. This represented a decided transition from the empirical to the scientific.

Toward the end of the third decade of the nineteenth century, dentistry in America was receiving its first impetus and the scene of activity remains in America for a time. Chapin Harris started the first dental journal among a register of only two hundred, and in 1839 the first dental school was organized. Reconstructive dentistry gathered much momentum in the decade following, with the introduction of the process of vulcanization, the application of which leads us into the second half of the nineteenth century. These were eventful days. The porcelain furnace and porcelain inlay were introduced by Jenkins; the use of porcelain teeth upon metal bases reached its height of artistic expression with the continuous gum denture; the substances for partial tooth restoration were undergoing much experimentation and many changes. Silicate cements were being employed. The defects of amalgam were beginning to be recognized. Sir John Tomes, who alone completed the histological data of tooth structures, was one of the leading figures in experimentations with amalgam; cohesive gold took the place of noncohesive; the pneumatic mallet and the rubber dam were introduced, and the dental engine was becoming a reality, although it was not really applied until 1870—a goodly amount of creative and constructive endeavor in a period of little more than three decades.

What was the state of consciousness of the dental practitioner at this time? He was treating caries by mechanically removing the decay, leaving a formless cavity which he attempted to seal with some substance that would resist the stress of mastication, would not interfere with occlusion, would be resistant to the fluids of the mouth, and would be so inserted that the ingress of moisture would be prevented. These requirements were being met by the gold filling. There was no consideration as yet for asepsis. Pasteur at this very period stirred the world with his method of sterilization, which had as yet not been applied. There was no consideration for the formation of a cavity that would meet the requirements of the laws of physics, in being resistant at every point within that cavity to the forces of mastication from all directions, in being retentive, and in being designed to include an area of extension for the prevention of subsequent secondary decay. He was not concerned with constructing his filling to replace anatomically the part of the tooth which had been destroyed, he was not concerned with conforming accurately to the normal relationship with its adjoining member and restoring occlusal balance.

The denture was at this time being applied all over the world. Vulcanite took the place of the metal base for two reasons: first, the process was much simpler, and secondly, it was less expensive. It was, however, being carelessly adapted over ragged roots, encroaching deliberately upon gingiva, producing, together with the destructive effect of the clasp, a decidedly uncomfortable reaction on the patient, which reflected back to the dental practitioner.

And now the shell crown and the fixed bridge were introduced. It is not difficult to understand why the new method found such esteem in the eyes of the laity, why such slogans as "Have a shell crown placed upon your tooth to insure it against further trouble," or, "At last we can put teeth in your mouth that can stay in and feel like your own," were so deceiving. Now it is difficult to understand why the American dentist and American dentistry fell into disrepute with their English friends and with a small voiceless minority in America. A movement frequently receives impetus through some destructive phenomenon. For two decades fixed appliances held uninterrupted sway. American dentistry was the fashion. Its influence spread, especially in France and Germany, and the toll was and still is heavy.

Constructive endeavor was not entirely lost. It continued to exist in England. Sir John Tomes remained the guiding spirit. The silent dissent of the small minority in America found expression at first in criticism and then in a new vigor of creative and constructive effort, which was crystallized in the contribution of Dr. G. V. Black, who imparted the results of his keen observations regarding, particularly, the detailed anatomical formations of teeth and their relationship to each other; and who, with his consideration and application of the physical laws, placed the conception and technic for the cutting of cavities upon a definite scientific basis, that is today universally accepted but by no means universally applied.

The criticism regarding fixed crown and bridgework culminated in an article by Dr. Herman E. S. Chayes (1), from which the following is an excerpt:

"Crown and bridgework has been the worst sort of a makeshift, and if at times its destructive work has been hidden in a period of temporary satisfaction, it has been no less destructive in the end. It has become apparent, upon close study of the dynamics, physics and relations involved that no important point necessary to the success of the appliance, and essential to the physiological wellbeing of the patients and to their hygienic integrity has been considered, except, perhaps, the one requirement of filling the space which is devoid of dental members."

The language is clear and meaningful. It was a condemnation, not only of the one type of fixed crown and bridgework, but of the numerous variations that had sprung up in an effort to get away from the destructive effects of the system. The new objective was hygiene; the appliances were designed to be removed. Their construction, however, was similar in form to the fixed appliance and similar in principle. Their effect was no less destructive. They did not attain their objective of hygiene. In fact, the terrible amount of undue stress exercised against the abutments every time the appliance was removed and placed into position, served to undermine the supporting structures much more rapidly than the fixed appliance. Dr. Chayes's criticism was, however, at the time productive of no further good. Criticism was to be effective in another form which followed immediately after.

In November of the same year, at McGill University, Montreal, Dr. William Hunter delivered his now famous lecture (2). The question of oral infections and their constitutional effects were not new to Dr. Hunter. His keenness of perception had directed him to that conclusion some twenty years prior to his 1910 address; nor was it new in England, where dentists so early had the benefit of Dr. Hunter's investigations. But it was new in America.

"Septic American dentistry" branded the soul of American dentistry. "It is not a matter of teeth and dentistry. It is an all important matter of sepsis and antisepsis that concerns every branch of the medical profession and concerns very closely the public health of the community." And teeth ceased to be a matter of local consideration; they became an integral part of the entire constitution. To minister to the care of teeth meant to minister to the health and life of the human being. That was the purport of Dr. William Hunter's address. His facts were too startling, too convincing—his indictment was complete.

The material effects precipitated by this revelation were interesting. It was as if a bomb had been cast in the midst of the medical and dental professions. Hunter's data were feverishly confirmed. The medical profession began to understand maladies that had hitherto been obscure; a large group of dental practitioners attempted to shift individual responsibilities to legal and educational authorities, who both sanctioned and taught them the methods; another group assumed its responsibilities and set to undo its failures; and the hitherto small voiceless minority continued with its creative and constructive endeavor, now gaining considerable proportions.

Among the memorable achievements of this period was the invention of the casting process, by Dr. William Taggart. For many years Dr. Taggart had been experimenting with the series of steps comprising the casting process. He set definite standards for himself, which he finally executed. The need of a wax that would be homogeneous, plastic, and hard for moulding and that would leave no residue within the mould after dehydration; the need of a refractory compound that would withstand the necessary amount of heat; and the need of an apparatus that would, in one operation, manipulate the fusing of the metals and direct properly a definite pressure to drive the molten metal into the mould; those were his standards. The profession later received the carefully completed process, which is today generally applied in the United States. The casting process made the inlay a reality, which superseded the gold shell crown, and is superseding the gold foil filling. The use of the gold foil filling is becoming rather limited because of the trauma produced by the constant percussion with the mallet against the vital tooth, besides the great length of time needed to introduce the pellets of gold leaf under uncomfortable strain, and because of the difficulty in restoring proper anatomical contour.

Important natural phenomena were at this time observed by Dr. Chayes, namely, that teeth are not fixed entities within their sockets; that they have a definite movement essential to the health and vitality of the tooth and the tissues surrounding it; that this movement takes place during function, and that to fixate any number of teeth into a single mass would prevent the natural movement of those teeth, which would in turn produce a condition of stasis of the surrounding tissues by cutting off the stimulation of the blood supply. One need but cite a simple illustration—the ligating of a number of fingers into a rigid mass. Function is immediately impaired, which in time leads to stasis and subsequent atrophy. It was essential, then, to produce a reconstructive appliance that would have the following features:

1. An appliance that would not inhibit the natural function of the teeth.

2. That would not transmit any undue stress to the abutments, during function.

3. That would not exercise any undue stress against the abutment teeth either when placed into position or when removed from position.

4. That would be hygienically clean.

5. That would not cause any irritation of the gingiva or the underlying tissues.

6. That would not necessitate the promiscuous devitalization of abutment teeth.

Dr. Chayes succeeded in developing a universal method embodying the above mentioned requirements. His system of movable, removable bridgework consists of a series of attachments of various sizes designed to be placed in a buccolingual direction within the normal contour of inlays cast against cavities prepared as prescribed by Black. The thinness of these attachments permits the removal of no more tooth structure than would be necessitated in the preparation of a typical proximal cavity as outlined by Black. The relationship of these attachments inserted within the inlays must be a perfectly parallel relationship. This is accomplished by means of an instrument, known as a parallelometer and designed by Dr. Chayes. The instrument consists of two horizontal planes, one moving upon the other and controlled by an actuating screw. The planes hold a number of clamps with clamp grooves which hold mandrels designed to fit accurately into the attachments. The attachments are thus carried by their mandrels into position within the inlays, the proper distance between the abutments being established by the movement of the actuating screw and the absence of complete strain being checked by the tactile sense of the operator. When the position of the attachments is thus established, they are secured, the instrument and the mandrels are removed, and the attachments soldered to their inlays. These attachments, known as the female portion, have their counterparts, the males, which fit accurately within the jackets. The male parts are attached to the sides of the bridge portion which consists of the number of teeth to be supplied upon a saddle cast against the edentulous tissue. The saddle is designed to cover and include the same amount of tissue area as had been engaged and stimulated by the roots of the natural teeth. The underlying tissues of the saddle receive the stress during mastication, because of a designed give or yield in the relationship between the male and female parts of the attachments.

Observations on the Existence of Abnormal Physical Conditions as Shown by the Teeth*

By WAITE A. COTTON, D.D.S.,
New York.

There are teeth to be protected against decay and pyorrhea, as well as teeth to be restored to usefulness from decay and pyorrhea. In other words, "An ounce of prevention is worth a pound of cure."

Since the first dental college was established in Baltimore about 1842, the dental profession has confined its activities to repairing, removing and replacing teeth, with vague and conflicting ideas of preventing these conditions. It is natural that this should be so, for dentistry has not been and is not even now considered a branch of medicine. There are various reasons why the dental profession has been circumscribed in its progress from the medical side, and also why so many of its members still adhere to the belief that all the causes and cures of oral conditions are contained in the mouth.

Dr. Pottenger in the preface of his book, *Symptoms of Visceral Disease*, says, "Though I have devoted myself to the study of diseases of the chest—a socalled specialty—for more than twenty years, experience has led me to see that such a thing as a medical specialty in the accepted sense of the term cannot exist. Diseases cannot be divided into those of this and that organ; for the human body is a unit. One part cannot be diseased without affecting other parts. No organ can be understood except in its relationship to other organs and to the body as a whole."

During the past few years we have learned to our chagrin that a good part of the repairing and replacing has been septically performed, with the result that the medical men have not been backward in calling our attention to the systemic conditions that have resulted.

We now wish to call the attention of the medical profession to the fact that dental decay and pyorrhea accompany the lack of coordinate function of the body as a whole and that a small part is of local origin, and it is up to the physicians to cooperate with the dental profession for its control.

There are two sides to dentistry—the mechanical and the medical. As dentistry originally was entirely mechanical, development has been the greatest along this line, while we have been careful not to encroach on the medical for two reasons. First, we have been too busy developing and selling our mechanics. Second, we are not a branch of medicine, and zealously have been taught and have believed that everything connected with our profession was contained in the limited area of the mouth.

As our study in dentistry penetrates deeper into the problems of oral conditions the fact stands out with ever increasing emphasis that the human body is a unit and incapable of real division into specialties. The preeminent man in dentistry of the future will not be the scientific laboratory worker, or the exodontist, who is most skillful in removing teeth, or the orthodontist who can perform wonders in regulating, or the specialist in periclasia who can most skillfully remove all deposits from the teeth, or the prosthetic specialist, who can rival nature in the beauty and usefulness of his restorations, but the man who recognizes the fact that the truths derived from all these sources of study and investigation with the observations of the systemic conditions that cause or accompany the necessity for the specialists in these branches; in other words, the man who studies and interprets the human body as a whole in relation to dentistry.

The specialist should be one who regards his field of study in its intimate relationship to the body as a whole. The dentists of fifty years ago were good mechanics and good clinical observers as far as the mouth was concerned, but they were not armed with many of the scientific facts which form the basis of modern dentistry. Consequently it was dentistry founded upon mechanical restorations of the teeth with little clinical observation of oral conditions and practically none in their relation to the body as a whole. Is this to be wondered at, for the dentist, jealous of his profession, was taught little of general medicine and did not consider that he needed it. Some physicians did not consider that the teeth were important and in turn were not sufficiently interested to even learn their names.

---

*Read before a joint meeting of the Syracuse Academy of Medicine and the Syracuse Dental Society, May 7, 1922.

The belief that the cure for dental decay and pyorrhea is entirely contained in the oral cavity is still held by many of the profession. Most men change their opinions with difficulty, even though they have never examined the reasonableness of these opinions. If it is painful for a man to leave the home where he has spent most of his life, it must be still more painful to break with his old education. The status of all business, profession, or science depends upon a mass of established and accepted facts, which may be true or not, but as far as their influence is concerned, they dominate it. An advancement is only made as increased knowledge shows that some of these socalled facts are errors.

We have endeavored to evolve dentistry through the laboratory of scientific research, in dental pathology, bacteriology and histology, so that today we are looking almost entirely to the development of these specialties to answer our problem of oral conditions, while we have ignored the clinical observation of the mouth in relation to the body as a whole. While fundamentally there can be no antagonism between the scientific worker and clinical observations, they must be brought together for the building of a unified dentistry of the future. The one outstanding need of modern dentistry is accurate clinical observations and interpretation. I do not mean to underrate all the laboratory has given us or be ungrateful for it, but clinical observations have not kept pace with the laboratory work for the reason that the dentist did not think he was a branch of medicine and that he was only a "tooth carpenter" and for that reason he had no right to encroach upon the territory of the physician to do any clinical observation of the teeth in relation to the system as a whole.

Dentistry has developed unevenly. Scientific laboratory work has been an inviting field, for there have been so many lines of investigation that could be done without the inconvenience of the examination of numerous patients, while the dentist in general practice who comes into contact with patients has not the time for such examinations and frequently has not the knowledge or the inclination to make accurate clinical observations.

To correlate properly all the facts that have been given us by scientific workers and the clinical observations of the past and present, we must link these two together with practicality and common sense, and thus eradicate errors and false theories that may creep in. Dentists must be familiar with all the laboratory facts and the method of obtaining them. They must cultivate the same accuracy of observation as the laboratory worker. The patient is the subject of the clinical observation with all the departures from normal function and all the abnormal tissues, secretions and excretions, found upon examination.

There can be no doubt that great inaccuracies are bound to occur in data obtained through clinical observations of patients. Much of this inaccuracy arises from our lack of knowledge, partly to inaccurate observations, and somewhat to misinformation furnished by patients.

If we compare clinical observations and interpretations with our scientific data, we will find there is not so much difference as one would expect, especially if they are joined with a little common sense.

As an illustration I have a patient who is a professor, and I suggested to him that I would like some way of preventing dust from collecting on top of my cabinet. He replied that that certainly could be done and he would help me. So the next day he appeared with a piece of glass six inches square which he placed on top of the cabinet for the purpose of collecting dust. He then measured the distance above the cabinet to get the cubic amount of air over it. He then took a sample of some of the air containing the dust back to his laboratory. He informed me a few days later of the chemical composition of the dust he had collected, how long it took a certain amount of dust to fall one foot, how long it would take to collect a centimetre of dust. He had also investigated the neighborhood and found that this dust was produced by automobiles in the street, the smoke from nearby chimneys and some kicked up by the dog in the next yard. He suggested that we have smoke consumers or screens put on the chimneys, the dog sent to the country and automobiles kept off the street. If these suggestions were complied with, he felt sure that the amount of dust would be appreciably lessened. I asked him what he thought would happen if I closed the window over my cabinet. Wouldn't that be the common sense way of eliminating most of that dust? He might say, "I never thought of that."

The scientific theory of medicine as put forth in the medical books and practised in 1790 was—if a patient is ill, bleed once. If not better, bleed twice. If still no better, bleed three times, for it is better to live weak than to die strong.

Today with our more advanced knowledge we smile at this theory, and yet with all of our advanced science we may be as far from the correct treatment of some conditions as they were in 1790, for we have not as yet reached the point where the ultimate goal can be realized, but a sure way of advancing toward the ideal is to use practical methods in the application of science.

Too many physicians do not regard the dentist as other than a local mechanical specialist, and many dentists themselves regard the process of dentistry as merely a mechanical adjustment. They do not pay enough attention to conditions at their inception, and are prone to overlook minor ailments and adjustments which if not recognized may become a serious condition. They do not realize that the conscientious observing dentist may be able to develop from his experience valuable diagnostic observations.

There has been in the minds of both laity and the professions a tendency to concentrate on the ailment or defect of one or another particular manifestation and overlook the working of the machinery as a whole, in other words, to quote a medical editorial "an overdone specialism."

Referring to our first paragraph that there are teeth to be protected from decay and pyorrhea as well as to be restored to usefulness from decay and pyorrhea, for the past few years I have been correlating clinical data based on scientific facts. There is no doubt there is a certain amount of error in the interpretation of these observations, but if I can stimulate other members of the profession to work along similar lines there is no doubt that the time will come when we shall be able to control dental decay and pyorrhea as well as the physician controls understandable diseases. There can be no doubt to the careful observer that pyorrhea and caries accompany systemic conditions.

The resistance or tone of the gums or investment tissues of the teeth and the attributes of the protecting secretion in which the teeth are bathed must necessarily be dependent upon the systemic conditions, for they do not derive their blood and nerve supply from the circumscribed area of the oral cavity, but from the body as a whole.

Dr. Carrel in his experiments on the cells of the chicken embryo was able to keep alive for many years undifferentiated tissue cells, by protecting them from infection, poison and trauma, and these cells when properly nourished and protected apparently have an indefinite lease of life.

None of the organs and cells of the body is as perfectly protected and nourished as those in Dr. Carrel's experiments. Consequently we do not have an indefinite lease of life, for we are not carefully nourished and are open to all kinds of infections, poisons and trauma. These infections, poisons and trauma would have comparatively little effect if we had the proper resistance and tone to our bodies, the major part of which is due to heredity, toxic substances, diet and endocrine secretions.

So far as the individual is concerned, heredity may profoundly influence the quality of his tissues, his organs and his underlying resistance. Outside of syphilis, there are hardly any diseases that are hereditary, but a weakness in any of our organic functions may be hereditary, and those weaknesses may lead the same disease to be produced as in the parent, but the disease itself is not passed on by the parent.

A toxic substance is any substance taken into the organism or so changed or manufactured in the organism that it produces an accelerating or inhibiting effect upon any cell or group of cells causing impairment of function. There are three ways in which the body becomes surcharged with substances it cannot use. First, by the mouth in the form of excess or unusable food products. Second, by being manufactured in the body by microorganisms. Third, by the lack of elimination of the waste products of cell metabolism. If these waste and useless materials which are toxic substances are not entirely eliminated, then they must of necessity remain in the body and will have their influence upon the different tissues in proportion as they increase, affecting the secretions as well as lowering tissue resistance.

Emerson said, "Human beings are as lazy as they dare to be." As human beings are only an aggregation of cells, it is obvious that the cells would have the same characteristic of being as lazy as they dare to be, which might be another reason for lack of sufficient elimination of our waste products.

In my discussion of types and textures interpreted in terms of endocrinology or glands of internal secretion, I realize that I am treading upon rather new and controversial scientific ground. I am, therefore, in my observations giving the average consensus of several authors, leaving those who disagree to fight it out with these writers themselves. Coming back to common sense again, these observations work out in the case of the teeth and their ailments and care, and that is my particular interest and point of view.

In the endocrines there are three more prominent types, the thyroid, the pituitary and the adrenal. These vary according to the influence of the other glands. The secretions of all the glands vary from undersecretion to oversecretion.

The thyroid facilitates energy productions. It also has an antitoxic function, its power being to increase the resistance to poisons and bacteria. The feeding of meat to an animal deprived of thyroid shortens its life, so it must assist in the prevention of autointoxication. The thyroid type has bright eyes, clean, hypersensitive teeth, pearly, small and regular, moist skin, tendency to heart, intestinal and nervous diseases. Subthyroid persons are more susceptible to alcohol, morphine, cocaine and novocaine than normal or hyperthyroid. The subthyroid person is stupid and they have unclean mouths and caries of the teeth.

The pituitary contains two glands in one, the anterior and the posterior. Most investigators agree that the anterior lobe of this gland has the greatest influence on the growth of bone, the connective, and supporting tissues, while the posterior part of the gland seems to have control over the tone of tissues, such as the involuntary muscle fibres of the intestines and bloodvessels. It will increase the blood pressure and the flow of urine when injected. It assists in the rate of metabolism or tissue combustion, which is the use of energy. An excess of the secretion of the anterior lobe before puberty results in the elongation of bone. The teeth are large, irregular, square, with prominent centrals. The pituitary predominance seems to control the size of the centrals. The hyperpituitary person has square protruding jaws, high nose and well marked cheek bones. There is a tendency to periodical diseases. The teeth are long and square with a marked separation of the anteriors, little or no caries. In an undersecretion of the anterior lobe the body is small and the patient usually fat and lazy, teeth usually oval, small, carious and crowded. A subsecretion of the posterior lobe usually allows pyorrhea to become existent from lack of stimulation of tissue tone.

The cortex of the adrenal is the outside or bark and is supposed to control the growth of the brain cells, their number and complexity. Besides its action on the sex and brain cells it has an action on the pigments of the skin which increases or decreases its sensitiveness to light, so that the color of the skin, whether blond or brunette, is looked upon as being controlled by the cortex of the adrenal glands. The secretion of the medulla is adrenin, which is supposed to control combat and fear. In the case of fear, which underlies a desire to fight, a small quantity of reserve adrenin is released into the blood, which in its turn takes the blood away from the intestines, liver, spleen, skin, and other organs, and sends it to the muscles. It also liberates sugar from the liver, as the cells can get energy rapidly from sugar. Adrenin is also antagonistic to fatigue.

Adrenal excess is usually accompanied by high blood pressure and a great capacity for work without the usual fatigue. The teeth are well developed, tending to the yellowish color, with premature eruption. In the subadrenal types, the dentition is delayed. The size of the cuspids seems to be proportionate to the adrenal activity. Long, sharply pointed cuspids are indications of well functioning adrenals. The adrenal person is hairy, dark, has a tendency to diphtheria and hernia. The face is usually dark, irregular and hairy.

These are three principal or master types. The gonads, pineal, parathyroids, thymus, mammary, spleen and pancreas all have their effects on the teeth. Decayed teeth will usually accompany a condition of undersecretion.

The thymus is thought to affect the nutrition of the body during childhood, for the teeth are youthful, thin and translucent, crescent or scalloped at the biting edge and of a milky white color, and will decay if the secretion is sufficiently subnormal.

The gonads also have an internal secretion. The lateral incisors are nearly always distorted or irregular when these glands are inferior. When the laterals are missing in the male, the glands are weak. In the female the ovaries are usually affected. A hypersection will accompany pyorrhea.

The parathyroids have control over the lime metabolism, for where there is a lack of secretion the teeth fail to develop properly, particularly the enamel, for which lime is essential.

The endocrine secretions have an underlying influence in the growth of every person, the size of the skeleton, the proportion of the size of his arms and his legs, whether he is tall, short, thin or fat. In the skull, whether the forehead is to be broad or narrow, the eyes close together or wide apart, the size of the nose, jaw and the peculiarities of the teeth, the skin, its color and quality, and the mucous membranes all show this influence.

DIET.

Diet has as much to do with caries and pyorrhea as any other factor. A patient living on a meat diet, with breads high in starch and carbon, few or no vegetables, especially no raw ones, continued over a long period, will certainly have scurvy, pyorrhea, and decayed teeth. Such patients will naturally improve on a course of fresh foods, onions particularly, with little bread and no salt, while drinking plenty of lime juice and water, with plenty of oranges, apples and other fresh fruits.

Foods in themselves do not give us strength nor vitality. If they did the more we ate the longer we would live and the stronger we should be. Our strength and vitality come from our cells. They manufacture it from obtaining proper foods, and if we do not give them proper foods, they not only cannot manufacture strength and vitality, but they have to use a large part of the strength and vitality they have in eliminating useless and excess food material.

A balanced ration is required by the normal body, this balanced ration being composed of a number of foods. Very few of us ever get it, for the reason the people who prepare our foods either do not know how to prepare balanced rations, or else we do not know or care enough to ask for it, as long as we can get the foods that tickle our palates.

A great many of our troubles are due to some form of indigestion, which may have little or nothing to do with the stomach itself. The only true digestion is cell digestion. The only purpose of the stomach is its action in doing its part in preparing the foods that they may be converted into fluids and be absorbed by the blood, which carries these prepared foods to the cells in different parts of the body. As supplies of blood pass around, the cells take what they need, if they can get it. One source of neutral troubles is that the cells—like the body as a whole—are fatalistic in instinct. If they cannot get what they want, they will do the best they can—take the next best thing that offers, although the same next best thing may be the slow poison of uneliminated waste products of cell metabolism or other material that may have a toxic effect.

In dental caries the teeth must be necessarily protected by the secretions which continually bathe them. As has been written and discussed before, the saliva from the parotid, sublingual and submaxillary glands is not this secretion, as it varies materially in the quantity and quality of its component parts. It is obviously not possible to have a protecting function on account of its variability. The secretions of the mucous glands of the tongue, cheeks and lips are the protector of the teeth, and these secretions accompany the variations of the other secretions of the digestive tract, and the variation in these secretions may be produced the same as in pyorrhea by heredity, toxic material, diet and the endocrine secretions.

The color of the tongue in adult life is a reddish pink. A bright red glistening tongue is usually a symptom of disease. When the tongue is covered with a thick yellowish coat and a bad taste in the mouth, the mucous glands are not producing their proper secretion and this is an indication of derangement of the digestive organs. The whole alimentary mucous membranes are in close physiological connection. Any disorder of the stomach that will produce a furred tongue usually indicates something is wrong with some of the other organs of the digestive tract. A deranged mucous secretion is not responsible for all the decay that takes place. Traumatism, incomplete or imperfect calcification, and incorrect relation of the teeth also permit decay.

In dental decay the relation of the different parts of the digestive tract and the areas of the mouth are about the same as in pyorrhea. In pyorrhea it is the lack of the eliminative function. In caries it is the area of deranged secretions that accompany dental decay. This derangement must remain over a sufficient period of time to allow decay to take place.

We should abandon forever the idea that the practice of dentistry is merely mechanical and not dependent on the pathological and physiological conditions of the body as a whole. To learn to use instruments deftly and skillfully to remove deposits from the teeth is essential from the mechanical viewpoint, but this is not enough, for the dentist of today must be something more than a mechanic and this can only be accomplished by a closer observation and study of systemic disturbances that accompany oral conditions and the localization of oral diseases.

Extensive Involvement of the Ocular Muscles Due to Focal Infection of the Teeth*

By L. WALLER DEICHLER, M.D.,
Philadelphia.

Focal infection of the teeth, as the direct or predisposing cause of disease of the various structures of the eye, has become a matter of increasing study. Its effect upon the external ocular muscles has received little attention and, in the few cases reported, single rather than multiple muscles were involved. It is my purpose to present for your consideration a case in which focal infection of the teeth appears to have been the sole cause, and in which there has been such extensive involvement of the external ocular muscles, that I believe it to be unique and perhaps of interest.

May I pause for a moment to remind you it is but a short time since Sir William Lang (1) had his attention called to a case under treatment for a general medical condition in which a keratitis seemed to be a separate entity, where the patient quickly recovered with coincident disappearance of the corneal inflammation when an infective pyorrhea alveolaris was discovered and corrected.

His study and report of a series of ten thousand cases of disease of the eye and its appendages due to focal infection followed, wherein our attention was called to the fact that focal infection wherever located, but pyorrhea alveolaris especially, caused inflammation of every part of the eye, the uveal tract being involved in about fifty-three per cent. of all cases.

Since then, valuable papers have been contributed by Benedict (2), Bedell (3), Stallings (4), and a host of other observers, so that it is now recognized that many types of disease of the eye are caused, either directly or indirectly, by diseased teeth or their surrounding structures; that these may be of any degree of severity and that cure is often effected, even in those of a chronic or recurrent type, when the infected teeth are removed or the pyorrheal condition is corrected; that ocular changes resulting from dental lesions may be divided into two groups —organic and functional—and the organic may be subdivided into deep and superficial; that the histological variations in the structures of the eye determine whether they are involved by the bacteria *per se*, by the toxins of the bacteria, or by both; that uncorrected eye strain plays an important part in favoring localization in the eye of infection circulating in the blood. It is equally true that an eye after operation has lowered resistance which in the same way plays an important part in favoring localization of infection; that there is often a direct relationship between the eye affected and the location of the infected teeth responsible for the condition. This is true of the functional cases especially. Here the infected teeth are most often on the same side of the jaw as the affected eye and chiefly limited to the upper jaw; that the process of transmission of the infection from the teeth to the eye is in almost all cases problematical. Three pathways are recognized however:

1. Direct extension through bone. The tooth socket becomes the seat of an infection which destroys the bone of the upper jaw and, by direct extension through contiguous structures, reaches the walls of the orbit and sets up an orbital cellulitis which extends to the tissues of the eye itself.
2. Direct extension of the infection along the periosteum of the malar bone to the orbit.
3. Transference of the microorganisms or their toxins from the foci about the teeth to the eye by the blood stream.

In addition, may I particularly call your attention to the fact, there may be direct transference of the microorganisms from the teeth to the eye by the patient himself. This is perhaps more common than we think, especially in postoperative cases, and is to be guarded against. Rubbing the eye because it itches with a finger moistened with saliva has caused the loss of the eye, and, where the patient is instructed to carry out the treatment for himself, contaminated fingers are easily responsible for contaminated compresses and these in turn for an infected eye.

A diseased eye caused by focal infection of the teeth is at times but little influenced by extraction of the offending teeth. Infective material may be left behind in the sockets, perhaps with necrotic bone, or there may be secondary foci set up in other structures, as the tonsils, sinuses or gastrointestinal tract. These are just as dangerous as the infected teeth. Therefore each case should be referred to a dentist who is skilled in his work and the importance of thorough supervision impressed upon both dentist and patient. Too often the dentist is satisfied to pronounce the teeth negative because of external appearances and without an x ray being taken, or he is content with simple extraction of the teeth, paying no attention to what may be left behind and hence all infective material may not be removed. There is an added danger in stopping the flow of blood from the socket too soon. Nature is washing away the infection. It is sound practice to pack the socket that healing may occur from the bottom and thus avoid too early closing of the wound by sealing the top with retention.

We are warned against too vigorous dental treatment, as disastrous eye conditions have followed, especially in elderly people. Let us remember dental treatment is never to be carelessly done with excessive traumatism, but, on the other hand, it is possible that it is not extensive enough to insure removal of all infective matter and, in consequence of the trauma induced, this readily gains entrance to the blood through the portals thus opened up.

May I emphasize the fact that often an eye is operated upon too soon after the dental treatment attempts removal of infection. This, as has just been stated, is often imperfectly done. Allow sufficient time to elapse in every case that healing may be fully established, all secondary foci sought for and if found corrected, for an eye after operation is one of lowered resistance to any infection which may be circulating in the blood.

---

*Read before the Section in Ophthalmology of the College of Physicians of Philadelphia, February 16, 1922.

Case I.—Mr. W. K., aged sixty-five years, presented himself January 17, 1922, for examination, complaining of diplopia. His previous medical history was negative. The patient smoked ten to twelve cigars a day. The patient had felt somewhat dizzy at times for the past week. Last night, while watching a moving picture, he was seized with sudden vertigo, when he saw everything double. Closing one eye, sight seemed to him unaffected in either eye. but with both open he could hardly walk because of the confusion which followed. There was no pain or other subjective symptom and no history of trauma.

Examination—vision O.D. 15/50? and with correction 15/20?? O.S. 15/70? and with correction 15/30+.

The eyes were somewhat staring with widening of left palpebral fissure and left eye turned somewhat downward and inward. Conjunctiva and cornea were negative in both eyes. The pupils were equal; responded promptly to light, but right more quickly than left, and both respond quickly and evenly to accommodation. Consensual reflex was normal. Media was clear and fundus negative in both eyes.

Ocular movements: O.D.: No movement up or down in vertical axis; slight limitation to both abduction and adduction in horizontal meridian; limitation moving eye up and out; no down and out movement at all; limitation up and in with greater limitation down and in. O.S.: No movement up and but slight movement down in vertical axis; some limitation of abduction and slight limitation of adduction in horizontal axis; no movement of eye up and in; some limitation down and in; more marked limitation up and out as well as down and out.

With point of fixation directly in front of patient and at a distance of 10′ there is diplopia due to both exophoria and right hyperphoria. On approaching the patient the exophoria disappeared at one metre, and the hyperphoria was not as pronounced and at a distance of fourteen inches from the face this also disappeared, when but one object was seen. Point of fixation held at one metre from face; in right horizontal field the diplopia disappeared but in left horizontal field was more marked than when the object was in front of the face; in right upper field there was a wide separation of the images and in right lower field there was diplopia but images are not as widely separated as in right upper field; in left upper field there was still wider separation of the images and in left lower field the diplopia disappeared with but one image. In all of these the images were parallel with no demonstrable tilting and the hyperphoria much greater than the exophoria.

Subsequent history of this case was as follows: Wassermann reaction and uranalysis negative. Blood pressure was 100 mm. systolic and 60 mm. diastolic. Physical examination showed nothing abnormal. Dental x ray showed a marked absorption of the alveolar processes about the roots of all the remaining teeth with pyorrhea and pockets containing pus.

The patient was placed upon eliminative treatment and promptly referred to a dentist who immediately cleared out all suspected foci of infection. Twenty-four hours later he was much improved and next day the diplopia had disappeared but he complained of some slight blurring of vision. The muscles had apparently recovered fully. On January 25th at fifteen feet there was present 6° of esophoria with 3° of right hyperphoria, and on February 9th, 3½° of esophoria and 1° of hyperphoria. This has remained constant since.

From simple movements of the eyes it would appear that all the muscles of each eye were affected to a varying degree, with a complete paralysis of the superior recti in both eyes and the inferior rectus of the right eye, associated with almost complete paralysis of the superior obliques in both eyes.

From an analysis of the conjugate movements, however, I believe that this man had complete paralysis of the left superior rectus and right superior oblique, with marked weakness of the right superior rectus, left internal rectus, both inferior obliques and left superior oblique, associated with slight impairment in the action of the right internal rectus and both external recti, the latter two presenting the least disturbance.

That multiple muscles may be involved is borne out by the history just recited and that more than one muscle may be affected is substantiated by the following case:

Case II.—Mrs. C. H., aged twenty years, was carefully refracted about one year ago and glasses given. Repeated examinations of the muscles at that time revealed 6° of exophoria and 1° of right hyperphoria for distance, which did not vary but was of equal degree in each of the several examinations made, with orthophoria for near. On December 15, 1921, she reported to me complaining of vertigo and occipital headaches with eye fatigue, especially on near effort. At this time there was a tendency to carry head turned slightly toward the right shoulder. Vision in each eye was 15/12???.

Examination of each eye was negative except that in the left eye there were two small, pinhead spots of pigment deposit in the retina to nasal side and about one disc diameter from the nerve head.

There was no apparent increase in the divergence of the eyes and no demonstrable interference with the action of the muscles when the point of fixation was held at fifteen inches from the face, but a tendency to latent divergence had developed. There had always been good convergence with orthophoria for near; now convergence was maintained by slight effort. With object at a distance, however, there was present a tendency, with no apparent preference shown, for one or the other eye to fix while its fellow turned out. The exophoria was now increased to 9° for distance and 15° for near, with no hyperphoria.

General condition of health was good, physical examination negative, as were also the laboratory examinations. Blood pressure was 140 mm. systolic and 76 mm. diastolic. Teeth had been under observation by two dentists who reported them to be in good condition. X ray was requested of all the teeth. Throat and sinuses were negative.

Her symptoms progressively grew worse, nausea was added, and observation at frequent intervals gave a progressive increase in the exophoria so that on December 23rd there was 11° of exophoria and 1° of right hyperphoria for distance, and 20° of exophoria and 1° of right hyperphoria for near. There was now present 10° of manifest divergence, with marked latent divergence and a steadily increasing preference for O.S. to fix.

The patient did not have the x ray made, but now a right lower molar became painful, followed by an abscess and discharge of pus through the gum. This tooth was merely treated until December 29th, when there was 23° of exophoria for near and with left eye fixing there was about 30° of divergence of O.D. The offending tooth was removed. Two days later there was but 9° of exophoria for distance and 15° for near.

Her condition then slowly became better and on January 24th she had 8° for distance and 6° for near, with no hyperphoria. There was now no apparent limitation of the muscle movements of each eye, convergence was good, with much less latent divergence.

This, then, was a case where a muscle imbalance was made decidedly and progressively worse by an infected tooth. Here both internal recti were involved, but the right to a greater extent than the left.

Finally, to impress upon you the importance in insisting in every suspicious case upon an x ray being taken, irrespective of the dental examination and report that there is nothing wrong with the teeth, may I cite the following case as typical of what is frequently encountered?

Case III.—Mr. L. G., aged thirty-six years, presented himself complaining of the right eye feeling heavy and tired, and for the past week "a film" over his eye. He had never had as good sight in his right eye as in the left, however.

Vision—O.D. 15/70, O.S. 15/10? The external appearance was negative for both eyes. The cornea were clear, pupils equal and responded promptly to light and accommodation. O.D. Large and small floating vitreous opacities. Good red reflex, but no view of fundus obtained. O.S. Media clear. Disc margin blurred, with slight blurring of retina which had a granular appearance on the temporal side toward the macula.

General physical condition showed no demonstrable lesion and blood and urine were negative. Dental report was negative but no x ray was taken.

Condition remained much the same for three months. There was improvement but not a satisfactory one until an x ray was insisted upon, the report of which is as follows:

"There is a pyorrhea pocket, and some deposit on the anterior surface of the left upper second molar. There are apical abscesses at the roots of the upper central incisors. There is a pericementitis about the lingual root of the right upper first molar. There is a large abscess with necrotic bone about the roots of the left lower second molar and the left lower first molar. The left lower first molar has a remarkable deposit of calcareous material on the roots, of what is usually spoken of as exostosis. The lower left lateral incisor apparently has two roots, and both show abscesses."

Appropriate dental treatment followed, when marked improvement was obtained, so that a +1.50 cyl. ax. 60° gave 15/20 vision.

The patient still has vitreous opacities and a fluid vitreous which in all probability is a fixed entity.

The Prevalence of Oral Disease and Its Insidious Effect Upon General Health*

By BERTRAM B. MACHAT, D. D. S.,
Brooklyn, N. Y.

There are so many angles to the study and treatment of disease that we frequently overlook or leave the most obvious for last. It is but a few years ago that I vainly searched in textbooks for enlightenment on the teeth as avenues of infection; today, no treatise on pathology, bacteriology and related subjects would be complete without a comprehensive chapter on the various infective diseases of teeth and contiguous tissues and their immediate and potent effect in the production of systemic infection.

In this paper I intend to point out that the mouth, the gateway to the human body, hence the most obvious, is without a parallel as a portal of disease. The mouth is not only a mechanicochemical laboratory but also because of its unique relation to and position in the body, is subjected to natural, willful and accidental stress, thus rendering the parts within the oral cavity most vulnerable. While the soft tissues when injured are, like all other tissues in the body, susceptible to repair, this does not hold good of the teeth.

Teeth are end organs, and even though highly resistant to accidental damage and natural deleterious influences, nevertheless succumb; for, unlike any other tissue in the body the tooth is unable to successfully defend itself and is impotent in autogenous repair; hence, as we shall further explain, it becomes a primary factor of disease par excellence. This is especially true of the tooth whose formative organ, i. e., the pulp, is either diseased, devitalized or extirpated. Even where a healthy pericementum (or as it is also known the peridental membrane) obtains, such a tooth as I shall now point out is at least potentially pathogenic.

---

*Read before the Reading Medical Society, Reading, Pa., May 26, 1922.

The tooth which is intrinsically devoid of circulation (pulpless) while wholly incapable of defence, offers nevertheless ample pabulum in the form of decomposed organic tissues within its canals and canaliculi and other favorable conditions as to render such a tooth a perfect incubator. And since the natural crown is usually artificially sealed, drainage of disease products from the root occurs by way of the apex into a richly vascular subdental tissue whence communication with distant parts is readily established by the lymphagenous or hemic routes. It will be seen, therefore, that unlike any other part, the dental root canal presents an unrelenting focus, and even though the infection may be of low grade (generally, but not always) given sufficient time it will break down the bodily defences and ultimately defeat the host. In addition, we must consider the multiplicity of chances of infection from these sources as may be expressed in the number of root canals which in the normal dental complement is variably about sixty; so also the common almost universal occurrence of one or more such apicodental foci of infection in the life time of any person, and its ultimate cumulative effect.

Notwithstanding the fact that considerable literature has appeared of late pointing to the peridentally healthy pulpless tooth as harmless, we cannot share in such claims, for our own investigations have proved the contrary to be true. Intrinsically devital teeth, regardless of root filling efficiency, or of apicopericementai conditions have in our hands, on incubation, almost invariably yielded positive cultures. Such teeth (commonly known as pulpless or devital teeth) practically always yield streptococci in pure culture and but rarely give any symptoms by means of which the patient or physician may become alarmed. This may further be substantiated by the comparative infrequency of the acute apicodental exacerbation which is generally held as a manifestation of high resistance and probable limitation of the infection. Even here, when chronicity is established, until the pathological tissue is removed, recurrence of infection will supervene.

Yet, in the face of this extraordinary condition we speak of phagocytosis, inhibition and immunization. We can conceive of a focus elsewhere in the body being arrested or obliterated; that is, where body defences may be overwhelmingly organized to combat bacterial invasion, but the intradental focus is unique, since at no time can these body defences destroy the prolific last one streptococcus which inhabits the deep recesses of the dental canaliculi. So, to repeat, is it not clear that the dental focus as an initiatory source because of its guerilla warfare is incomparable in the body? Even its running mate, the tonsil, when infected, cannot be proved to be causative or resultant. In passing, it should be stated that unimpaired teeth are not infected by diseased tonsils; on the other hand we have encountered many tonsillar affections which have cleared up after the removal of diseased maxillodental foci. Therefore, it appears that when in search for the etiology of any general complaint many possibilities may present themselves as logical, but none will be found more concrete as a primary factor than the anomalous or infected tooth. For example, let us assume that the findings of an unbalanced blood chemistry, an engorged sinus mucosa, or a disturbed endocrine are substantiated, still their correction would be but temporary if the causal agent, the infected tooth, remained in situ. Let us assume also, that the aforesaid disorders exist coincident with a positive Neisserian or Wassermann test, would there be any speculation as to the proper course of procedure? Certainly antispecific treatment would be promptly ordered; why not pursue the same course where dental sepsis is found?

Dr. John E. Talbot, in an article entitled Focal Infection and Its Relation to Obstetrics, states: "So far as recent teaching has gone, Spirochæta pallida has been granted the exclusive privilege of passing the villous membrane and infecting the fetus." And further on he states: "Why should the spirochæte enjoy the exclusive privilege? There is evidence accumulating that this is not so, however, and once it is proved that other bacteria pass the villous membrane then a focus of infection capable of throwing bacteria into the maternal blood stream becomes a danger and a menace to the life and welfare of the fetus."

Referring to the common occurrence of mouth infection, Dr. E. Irons (1) asserts that "Infections of the mouth stand first in point of frequency as a cause of metastatic infection."

Talbot (2) states that nearly every baby, in which in his experience hemorrhage has developed, when newly born, the condition has come from a mother in whom he has been able to demonstrate foci of infection in teeth, and that a high percentage of such mothers have shown some signs of toxemia during their pregnancy."

Moorhead (3), in a study of 150 cases of systemic disease, found chronic dental abscess in eighty-nine per cent., pyorrhea in seventy-six per cent., alveolar abscess in sixty-nine per cent.

In the consideration of mouth pathology the average physician lays stress upon the gravity of pyorrhea alveolaris; still without minimizing the seriousness of metastatic invasion from this field, that is, the extradental focus, pyorrhea alveolaris when compared with closed dentofocal infection, is benign.

In the March, 1920, number of the *Dental Cosmos* I published the result of his bacteriological investigation of one thousand pulpless teeth. In this group are included only the symptomless type in which, to a great extent, is the pulpless tooth, concerning which there has been much discussion of late. The findings are as follows:

a. Mixed coccus infection is usually found in connection with cases of extensive apical involvement.

b. Devitalized teeth with negative radiographic findings, commonly yielded a pure streptococcus.

c. When specimens from several teeth of our patients were cultured, similar morphological grouping was found in all.

d. The same organism was recovered from the blood, in a few instances.

e. The presence of rods and spirilla on the microscopic slide is taken evidence of contamination, such findings having been rejected.

Richards (4), in the study of 104 cases of arthritis, found: in blood cultures, Streptococcus viridans in fourteen cases. Foci of Streptococcus viridans were found in teeth, fifty cases; tonsils, forty cases, and antrum, four cases.

It has been my observation in the oral treatment of patients who presented refractory general systemic complaints, where complete or drastic maxillodental surgery was performed, the results were highly gratifying. This was especially illuminating to me in instances where my patients were physicians of considerable experience and whose personal recoveries left little in point of speculation as to cause and effect. Some years ago I was called upon to treat a physician whose general poor health was aggravated by frequent spells of vertigo. His own experience as a consultant and the advice of the best medical talent attested to the fact that focal infection would be found the underlying cause. Several weeks after the removal of diseased teeth the doctor wrote me of his complete recovery.

A similar case presented itself several months ago. When I first saw this doctor he was in a very feeble condition. His mouth presented an extensive pyorrhea alveolaris in addition to many apically diseased teeth. There was considerable discussion concerning the safety of surgical interference; his physician finally decided that his only hope was in the clearing of the mouth from disease. Shortly after the removal of the first group of teeth his recovery was prompt.

It is not feasible here to go on with the citation of similar cases for this would make a very large volume, but generally speaking my study of over three thousand medicodental cases, now covering a period of nearly ten years, fully justifies the constant plea—investigate the mouth first, not last.

In the short time that the danger of mouth infection has become popularly known, much has been done and badly done. Like all new enterprises it has not yet found its proper balance. We hear of those who go to extremes in either conserving or removing teeth. Undoubtedly this is the result of misinformation and is largely due to lack of collaborative work. The medical man instead of looking to the well trained dentist for advice, takes matters in his own hands, refers the patients to a radiologist and then governs himself according to the x ray report in ordering teeth removed. Likewise the dentist who is not fully informed of the refractory conditions of the patient's malady is likely to take a more optimistic view, with the result that either harmless teeth are removed or dental tragedies are retained. Under these conditions recoveries are few and disappointments are many. Another militating factor is the manner in which teeth are removed. Unless complete eradication of maxillodental foci is resorted to, recovery is but temporary, relapse follows some months after extraction and the dental phase is apt to be dismissed as misguided.

These disappointments are probably responsible for the new hysteria which of late is appearing in our literature, "on the fallacies of the theories and practice of mouth pathology."

Many in our respective fields, who have given this question but a limited test, are relieving themselves of much rhetoric which in effect disparages and grossly minimizes the potency of mouth pathology. In view of the foregoing let it be said that herein, in these ambiguous and unproved statements which tend to befog the true issue, thus prejudicing the general practitioner against the removal of teeth in properly selected cases—lies the real danger; for the very progress that has been made in a field so tangible and productive of cures is thus being impaired.

It is clear that the time is ripe and the circumstances demand that men of both professions collaborate and coordinate their work more zealously in the practice of this borderline phase rather than in the indulgence of literary brilliancy.

In my own experience, wherein the physician's cooperation is part, we find that over sixty per cent. of our patients have improved or have been completely restored to health. Are they all accidental? Over eighty per cent. of a group of one thousand five hundred patients with two or more long standing sealed pulpless teeth, presented a blood pressure from twenty-five to thirty-three per cent. below normal, with a Talquist reading of from ten to thirty-five per cent. below par.

Space does not permit detailed statements of the foregoing, but is there any method in the treatment of disease that yields a higher percentage of success?

Or, are we again going to advance the hackneyed argument, i. e., the existence of many other possibilities in the production of these remarkable recoveries or circulatory conditions? In this paper I do not indulge in speculative statements or in farfetched theories. Nearly every one of the patients treated by me has had extensive, expensive, and exhaustive medical attention. That is why these patients present unusual interest.

In point of example I was called in to see a girl nineteen years of age in a dying condition—septic endocarditis was the diagnosis. She had been ill for several years. To my mind the numerous gold crowned abscessed teeth and two fixed bridges dating back to the time that she was eleven years of age told an eloquent story.

Three years ago the mayor of one of your nearby cities came to me with a widespread and exhaustive dermatological complaint. He was indeed very ill, barely able to walk and he suffered greatly when in sitting or lying down position. This condition dated back many years during which time he had the best treatment but apparently without avail. Following my examination I referred him to a dermatologist of wide renown with the request that he consider my findings and direct the management of the case. He referred the patient back to me the following day with recommendations to clean up the mouth of its pathology. We operated and removed several teeth and the man went home three days later greatly improved. He returned for further treatment and within a month he was back to work, the surface lesions disappearing while his general condition continued to improve. Lest the weight of this situation be not fully understood, let us compare the functional value of a tooth with that of a tonsil and the surgical risk of the former with that of the latter or a laparotomy, that we might realize how much greater is the risk in speculating with deeper seated pathology.

Oral Sepsis in Relation to Eye, Ear, Nose and Throat Disease

By LESTER R. CAHN, D.D.S.,
New York.

That oral sepsis has a malevolent effect upon the eye, ear, nose, and throat is well known. The anatomical relationship between the mouth and these organs renders them vulnerable to any inflammatory process in the jaws. However, all conditions are not due to the spread of infective material along natural channels, such as the Eustachian tube and the maxillary sinus, but the infection may be carried by the blood stream from a focus in the jaw to the eye, ear, and so forth.

Crow, an English otolaryngologist states (1) that in all probability ninety-five per cent. of middle ear troubles arise from infection passing along the Eustachian tube from the nasopharynx, and that it can readily be seen that many cases of otitis media, both catarrhal and suppurative, might occur as a result of oral sepsis. He records the case of a man thirty-six years old, who for three years had suffered from a suppurative otitis media and pyorrhea. A radical mastoid operation was performed, but the result was not as expected, pus being profuse for some weeks. Ultimately the teeth and gums were treated and his improvement was so marked as to leave no doubt as to the cause of the delayed cure. Since this case Crow has postponed operation, in every middle ear case, wherever possible, until proper attention has been given to the mouth.

Bellei (2) reports the case of a woman who had suffered from chronic pyorrhea for many years when symptoms of acute mastoid suppuration developed suddenly. She was operated upon for this condition but septicemia developed and she died. He was of the opinion that the mastoiditis was due to infection from the mouth.

Tinnitus is frequently due to oral sepsis. In this case it is a toxic neuritis. When the cochlear part of the eighth nerve is affected there is tinnitus, and when the vestibular portion is affected the result is vertigo. Impacted teeth are another source of tinnitus.

OTALGIA.

Pollitzer states that dental caries is the most frequent cause of otalgia in children. In cases of otalgia where there are no inflammatory or other abnormal phenomena in the ear itself to account for the trouble, the teeth should always be examined, as under such conditions they are invariably the cause of the complaint. Even where there is evidence in the ear to account for the pain, the possibility of the teeth being a contributory factor should not be neglected. Impacted and unerupted teeth are frequently the cause of severe chronic otalgia. Pressure of these teeth on the dental nerves would cause reflex pain in the ear.

DEAFNESS.

This affection, when there is no lesion in the ear, may be traced to an impacted or unerupted tooth. Mr. J. Howard Mummery (3) reports a most interesting case of deafness on the left side which had existed for some months. There was also delayed eruption of the third maxillary molar. The hearing was relieved to a great extent by the removal of this tooth, and fully restored on the same day.

TONSILLITIS AND PHARYNGITIS.

The tonsils and pharynx can become involved by direct continuation of an infection from the gums and oral mucosa. Hunter states that chronic pharyngitis is due, in a large percentage of cases, to oral sepsis, and in these cases the pharyngitis is usually coupled with a septic gastritis. G. J. Stewart (4) examined 231 cases of unilateral enlargement of the tonsil in school children. He found that in 135 cases there was dental caries, generally of the lower molars, and oral sepsis on the side of the affected tonsil; in 67 caries and oral sepsis existed on both sides; in 15 there were caries and oral sepsis on the opposite side, while in 14 there was neither caries nor oral sepsis. He states that unilateral enlargement of the tonsil is not found in infants. In the same paper he cites cases of laryngitis that cleared up by the treatment of the associated oral sepsis. Steadman, after examining a large number of patients afflicted with cancer of the throat and stomach, remarked that in every case of malignancy of the throat and stomach there was oral sepsis.

PURULENT RHINORRHEA.

Purulent discharge from the nose is often due to infected upper anterior teeth. There may be a fistulous tract leading directly from an upper incisor into the nasal cavity and therein discharging. We often find the upper anterior teeth penetrating the nasal floor. The following case is illustrative of this type of disease:

Case I.—M. S., aged twenty-eight, suffered from recurrent abscesses in the nose for a number of months. When these abscesses appeared they were lanced and for the time being he was comfortable. The frequent recurrence of the condition led to a search for the probable cause, and a radiographic examination was made of his teeth. The upper right central incisor was found to have a partly filled root canal and the apical bone was rarefied, indicative of a chronic infection. The upper left central incisor appeared normal in the radiogram but proved to be nonvital on clinical test. Upon opening up the left central incisor there was a considerable flow of pus from the canal. The area was drained and the root canal sterilized and filled. The upper right central incisor was also opened, the old root filling removed, and the canal sterilized and refilled. In over a year there was no return of the nasal trouble. The patient was fortunate in retaining his teeth. Inasmuch as they were front teeth, we decided to try and save them, and if there was no reappearance of the nasal trouble after the teeth were treated, we could feel assured of the success of our treatment. This is not possible, however, in every case. We often have to resort to extraction, or at least to amputation of the apex of the affected tooth.

The foregoing case is readily understood when we consider the close anatomical connection between the upper anterior teeth and the floor of the nose. The next case is more interesting because anatomically there is no relationship between the affected tooth and the seat of disease, and the resultant infection must have been borne by the blood stream.

Case II.—H. H., aged twenty-two, was referred for dental examination solely, no mention being made of any other ailment. Radiograms were made of the jaws and the teeth, and the right lower first bicuspid was discovered to have a large rarefied area apically, which we decided to remove. The tooth was accordingly extracted and the diseased area curetted. The wound healed uneventfully. About three weeks after the removal of the tooth, the patient said that the day following the extraction a purulent discharge from the nose, which had been treated for over a year and a half, had disappeared. It is now nearly two years since the removal of the tooth, and there has been no recurrence of the nasal disease.

MAXILLARY SINUSITIS.

Opinion is varied concerning the relative importance of the teeth upon the diseases of the antrum. Rhinologists place the teeth as the cause of about twenty-five per cent. of the cases of antral disease, while oral surgeons place the average as high as ninety-five per cent. It is generally felt, however, that infective conditions arising in the upper teeth are the greatest causes of maxillary sinusitis.

In any disease of the accessory sinuses of the nose, the influence of oral sepsis upon these conditions must be borne in mind. The mouth should be carefully examined, and if found diseased should be treated before any operative procedure upon the sinus is undertaken. As far back as 1850, Bond in his book entitled *Dental Medicine,* cites the following case which ended fatally.

Case III.—Miss W., a maiden lady of about fifty years of age, in comfortable circumstances and for the most part of sedentary habit, had suffered much from pain in the right cheek. For some time it was not considered of much moment, but on its continuance a physician was consulted. He found a single tooth, one of the second molars, in the superior maxillary of the affected side, and that was in a semidecayed state. The gums above the tooth and for a half an inch on each side of it were much swollen and of a vivid red color. The tumor seemed spongoid and fluffy to the touch, but there was neither fluctuation nor abscess. The patient's health had not sensibly deteriorated. She said the tumor on the gums had existed for many weeks, but had not been attended with any great pain, until the occurrence of the pain in the right cheek of which she complained. She described it as being deep in the cheek and generally dull, but now and then, for an instant, sharp and lancinating. She said the tooth for several years past, had ached occasionally, but that, notwithstanding its decayed state, it was very useful and she had declined having it extracted. The immediate extraction of the tooth was thought advisable, however, and with her consent, was effected. A week afterward the spongy tumor of the gum continued, without any abatement of the pain in the cheek. The tumor was now laid open with a lancet. It contained no matter but was filled with those shaggy or shreddy fungi which are often seen to occupy tumors or diseased bones. An abscess or some other affection of the antrum was suspected. A perforation was therefore made in its cavity, and a tablespoonful of very dark brown matter discharged, which gave the silver spoon into which it was received a thin coat of the blackest pigment, and on account of its offensive smell, was almost insupportable. There was difficulty in reaching the disease with remedies, and it was thought advisable to enlarge the communication with the antrum. The crown of a small trephine was accordingly applied to the alveolar portion of the superior maxillary, the soft parts having first been dissected, and a corresponding portion of the bone was removed. The end of the little finger could now be introduced into the antrum, the inner surface of which, it could easily be seen, had, at several points, been denuded of the pituitary membrane and the periosteum.

The disease was now fairly exposed, and nothing could exceed the offensiveness of its fetor when not corrected by suitable dressings. The usual antiseptics and detergents were applied locally, while tonics and a generous diet were prescribed to sustain the patient's general health, and every effort was made to substitute a healthy secretion for the ill conditioned and offensive discharge from the antrum, but without success. An irremediable necrosis seemed to have taken possession of the affected side, which soon began to come away piecemeal. In the meantime, the soft parts were laid waste by the phagedenic character of the ulceration, and the eye on the same side became seriously affected. The disease now progressed rapidly. The perforation of the antrum was made on March 11, 1821, and on May 28th, following, the patient was found in a perfect state of apoplexy, the disease having penetrated the base of the cranium and seized upon the brain itself. On May 30th she expired, and was thus relieved by death from the most horrible disease which can be conceived, but which had its origin in a neglected carious tooth.

DISEASES OF THE EYE.

Ocular disease as the result of oral sepsis is not by any means a modern theory. Fabricus Hildanus, a couple of centuries ago, reported a case of ophthalmia and loss of eye due to abscess of a tooth.

Blepharospasm is frequently occasioned by reflex irritation from the teeth. Excessive blinking is a mild variety of chronic spasm of the orbicular muscles of the eyelids. Colyer (5) quotes Knies as having seen a case of this kind cured immediately by the removal of a painful tooth. Colyer also expresses a most interesting statement when he says that blepharospasm occurring in old people having edentulous jaws may be due to an osseous sclerosis, causing spasm of the muscles reflexly by the imprisonment of the filaments of the dental nerves. Convergent strabismus is often associated with primary dentition. Myopia due to chronic contraction of the ciliary muscle will ofttimes be cured by the relaxation of the muscle after the dental irritation has been removed. Orbital cellulitis quite commonly occurs as a result of extension of an inflammatory process from the superior maxilla.

A fourth case will be included in the author's reprints; also his references.

A New Method for Directing the Central Ray at a Predetermined Angulation with the Aid of the Dental Methograph

By JOHN F. FREUND, D.D.S.,

New York.

The factors for accurate radiographic reproductions of parts have long since been established. The amount of current to be used, the force of the current, the distance from the target focal point to the object to be taken, the proximity of relationship between the object to be taken and the film, proper dark room technic, immobility of the parts during exposure, and the necessary angulation for the direction of the central ray through the object to be taken to the film, have all been formulated and reformulated innumerable times.

All of the factors mentioned above, with the exception of the last two, concern themselves directly with the production of contrast and detail and the last two, the immobility of parts and the proper angulation, concern themselves with an accurate reproduction of parts without distortion, either in a lateral or a longitudinal direction. The solution of these factors has ceased to be a problem in general radiography, but cannot as yet be dismissed in dental and oral radiography.

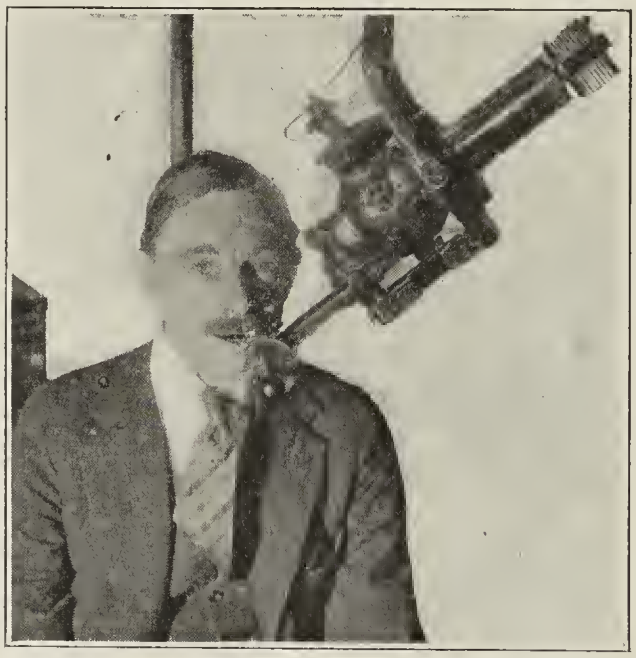

FIG. 1.—This represents the patient with methograph in position. The patient bites into the bite plane and automatically the film is placed in its proper position toward the area to be taken, while the x ray tube, with its holder suspended in air, adjusts itself by the pre-determined angular position of the methograph in the desired position toward the object to be taken and the film in the mouth. The bite plane with the impression of the upper and lower teeth is then filed, together with a record of the angular position, and by this means it is possible either to duplicate the original exposure or correct any further exposure that may be made.

On account of the peculiar relation between the position of the teeth and surrounding bones, particularly the superior maxilla, it becomes impossible to place the film directly against the tooth and the immediate surrounding tissues. Early in the experimental work of Dr. Satterlee and others, the formula for directing the central ray perpendicular to the line bisecting the angle between the long axis of the tooth and the position of the film was established. The difficulties encountered, however, in controlling the central ray, the slightest variation producing a distortion in either a longitudinal direction, or a lateral direction, were yet to be surmounted. More recently Dr. Van Woert, with his specially designed cone, succeeded much better in controlling and focusing the central ray, but again the procedure has not been accurate, the degree of angulation not having been accurately established.

The foregoing statements were prepared at my request by Dr. M. Diamond, of New York, and summarize the progress made in regard to the taking of dental radiograms.

The object of my effort from the beginning has been to create, by means of new mechanical devices, a technic for taking dental radiograms which would produce a true reproduction of the object to be taken. This is accomplished by a predetermination of the angle between the film and the object to be taken, and the relation of the central ray toward the object and the film. Such predetermination must necessarily eliminate the uncertain factors.

It has also been my aim to devise a simple method for accurately duplicating any number of dental radiograms of the same area at any subsequent interval of time. This method by means of its simplicity is to be within the reach of every dental practitioner.

By means of such a procedure the dental practitioner would be placed in a position to determine changes which have taken place during that lapse of time in the object or part taken, more accurately than can be accomplished by the use of methods previously known.

This method will make it possible to produce a dental radiogram, correct in its expression in regard to proper angulation. A record of the angulation at which the dental radiograms was taken by a technician would materially aid the diagnostician in making his proper diagnosis. Such a record would include the direction of the central toward the object to be taken as well as the angle between the object to be taken and the film of the mouth.

To acquaint you thoroughly with my ideas and the basic principles involved, I shall attempt to explain the changes from the present method brought about by my device.

1. The methods for taking of a dental radiogram, so far known, have three points of fixation. The x ray tube must be fixed in its holder upon the stand in such fashion that a firm rigidity will be maintained. The patient's head, that is, the object to be taken, must be rigid during the making of the exposure. Neither must the film in the mouth shift. The method I present has only one point of fixation—the x ray tube, the object to be taken and the film in the mouth are brought into one point of fixation by means of a bite plane.

2. The horizontal and vertical plane as well as a lateral shift forward or backward are also brought into one point of fixation by means of the dental methograph.

3. In taking stereoscopic dental radiograms the focal point of the x ray tube is no longer shifted the distance between the pupils of the eyes in a horizontal direction, but instead the object to be taken

and the film in the mouth are adjusted by a predetermined angular position toward the central ray of the x ray tube.

4. By means of the bite plane, the relation between the object to be taken and the film in the mouth is definitely established and if replaced can always be restored at any interval to its established original position. It is by this means that we are able to duplicate the original dental exposure, at any subsequent interval.

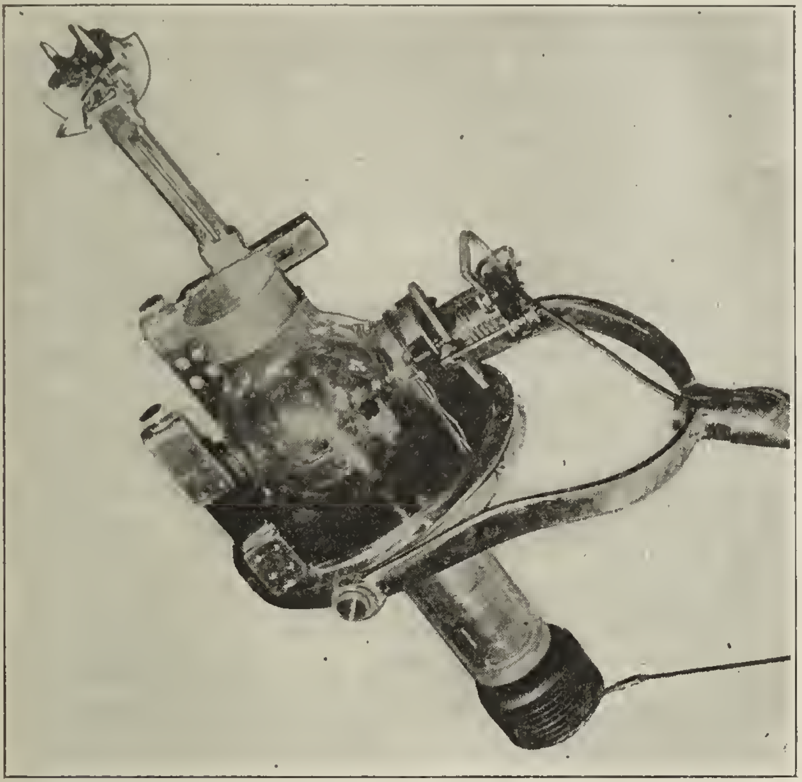

Fig. 2.—This shows the tube in its holder with the necessary device for placing the methograph in its proper position.

5. The methograph makes it possible to no longer focus upon the patient. The film is placed in the mouth in position facing the area to be taken and we then focus directly upon the film. (Figs. 1, 2, 3, 4, and 5.)

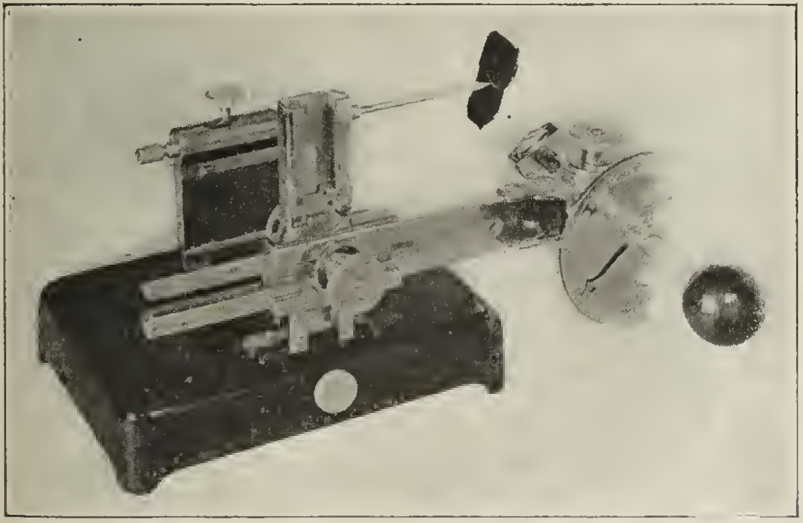

Fig. 3.—The methograph adjusted on its stand with film bite plane in place and pointer representing the main rays of the x ray tube, as well as the vertical tilt of the object to be taken, and the film in the mouth toward the main ray of the x ray tube.

The taking of stereoscopical dental radiograms is made possible by the simple procedure of shifting the horizontal angle of eight degrees when the distance of the target of the x ray tube from the object to be taken is between seven and eight inches. The shifting of this angle of the horizontal position is determined by the distance between the target of the x ray tube and the object to be taken. Let me say finally, that what holds good for the taking of intraoral pictures is also applied in the simplest way possible and under the same conditions for the taking of extraoral radiograms.

To make clear to you the extreme efficiency of the methograph, let me say that we are enabled, not only to duplicate at intervals any dental radiogram desired, but also can duplicate stereoscopic radiograms at any interval of time, something that no one else has ever been able to accomplish.

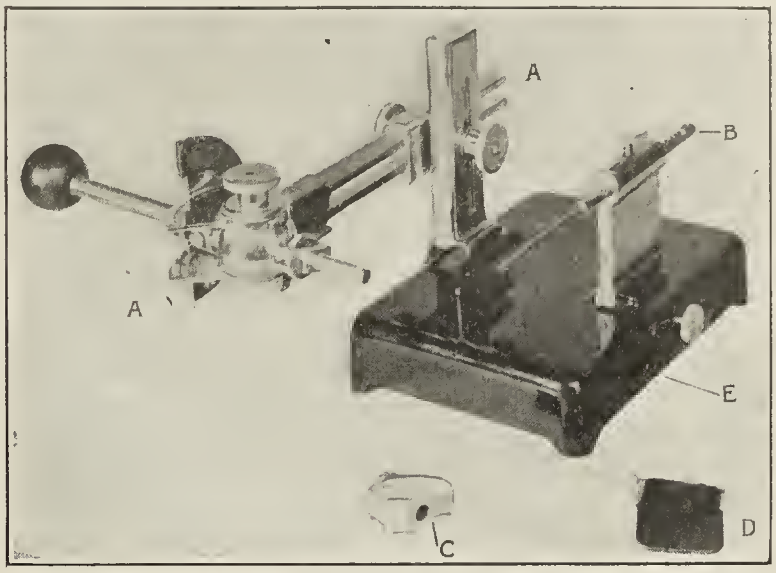

Fig. 4.—A. Vertical and horizontal plane, with lateral forward and backward shift, upward and downward movement, for the taking and recording predetermined position in space. B. The pointer representing the focal point of the x ray tube. C. The bite plane which is covered with modeling compound to record the bite of the patient. D. Film holder with film in position. E. Stand on which the measuring device A and the point of B is placed, representing the same position when A is placed in the holder of the x ray tube as B the pointer, representing the focal point of the x ray tube.

Before we dismiss this subject I wish to call attention to a vital fact, which cannot be given too careful consideration. This is, that what holds good for the use of the methograph in dentistry applies with equal efficiency to the use of the methograph in the practice of medicine. By means of this method the medical profession will be enabled to direct and control the central ray with absolute accuracy for both diagnostic and therapeutical purposes.

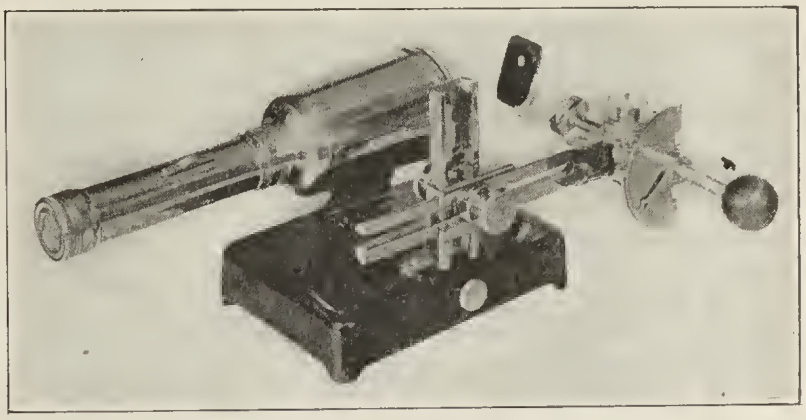

Fig. 5.—The pointer B is replaced by an electric light socket, representing the exact condition of the main ray of the x ray tube toward the film. This illustrates very precisely how accurately one is able to direct the main ray, no matter how small the shutter is, toward the object to be taken. One is thus always secure in directing the main ray precisely toward the part you wish taken, and by means of the diaphragm eliminating all unnecessary exposure of the x ray. In this way one has the privilege of exposing as much of the area as is desired.

In conclusion, may I hope that the presentation of my foregoing technic will add toward the standardization of the taking of radiographs, particularly in the direction of controlling the central ray.

ORAL SEPSIS

Little more than a dozen years ago, the pathology of teeth and their surrounding tissues held virtually no place in the etiology of organic diseases. Today the noninclusion of a careful examination of the buccal cavity in the general history and examination of the patient, no matter what the malady may be, is regarded as a serious oversight. While at the present time there may perhaps be a tendency to overestimate the importance of oral pathology in relation to certain specific diseases, it is really difficult to overestimate the importance of the part played by dental sepsis in establishing the etiology of constitutional disturbances that hitherto were obscure.

The responsibility of eradicating existing foci of infection from the mouth and the even greater responsibility of preventing oral sepsis rest with the dental profession. To rebuild, mechanically, the masticatory apparatus is a difficult problem; but while a normally functioning and properly balanced full complement of teeth is imperative, reconstruction of the dental apparatus is not to be effected in defiance of the normal physiological behavior of tissues, nor is it to be effected at the expense of oral asepsis. There have been sad mistakes in the methods of reconstruction employed, especially the shell crown and the fixed bridge. These mechanical contrivances enjoyed a vogue of more than half a century before the extensive pathological conditions produced in the mouth, and the resultant systemic disturbances, awakened the sensitive perception of two personalities almost simultaneously.

It is interesting to recall the expressive language used in a lecture delivered in 1910, at McGill University, Montreal, by Dr. William Hunter, whose part in establishing the relations between oral sepsis and systemic disease are quite familiar to us all. "It is not a matter of teeth and dentistry. It is an all important matter of sepsis and antisepsis that concerns every branch of the medical profession and concerns very closely the public health of the community. It is not a simple matter of neglect of the teeth by the patient but one of neglect of a great infection by the profession. Oral sepsis is more important as a potential disease factor than any other source of sepsis in the body."

And teeth and their needs ceased to be a matter of local consideration, they became an integral part of the entire constitution.

Equally decisive criticism appeared within the ranks of the dental profession, in an article entitled Empiricism of Bridgework, by Dr. Herman E. S. Chayes, which was published in the October, 1910, issue of *Dental Items of Interest*. He said: "Crown and bridgework have had a decidedly disintegrating influence upon the human economy; it has been the worst sort of a makeshift, and if at times its work has been hidden in a period of temporary satisfaction, it has been no less destructive in the end. It has become apparent upon close study of the dynamics, physics and relations involved that no important point necessary to the success of the appliance and essential to the physiological well being of the patients and to their hygienic integrity has been considered, except, perhaps, the one requirement of filling the space which presents itself devoid of dental members."

These critical attitudes are today assumed by both professions, after amassing clinical evidence, the compilation of which would fill volumes. And yet a great deal of sepsis is still being induced through improperly inserted fillings and inlays, and much more that comes under the head of dental reconstruction. The prevention of oral sepsis is a goal still to be attained. Just how it will be accomplished, the dental profession will eventually formulate. Perhaps a stricter observance of the principles of general surgery will be of assistance.

A MILESTONE IN DENTAL EDUCATION

The standards of education in dentistry have varied considerably since the first undergraduate school was organized in this country in 1839. For many years the dental school was more in the nature of a trade school, concentrating entirely upon the mechanical phases of dentistry with practically no requirements for entrance. Gradually the medical sciences were included in the curriculum of the dental school and the entrance requirements were becoming a selective factor. The establishment of dental schools as a part of such universities as Pennsylvania, Buffalo, and Harvard, removed the study of dentistry from the realm of the privately owned institution.

The rapid development in the various departments of dentistry made necessary a change in the curriculum from a three to a four year course of study soon after the world war, and considerably more attention was paid to the medical sciences in the new curriculum. The predental requirements, however, remained the high school diploma and in some privately owned schools, the regents equivalent in points. At this time the School of Dentistry of Columbia University was organized and took the lead in establishing new standards of education. The difficulties of reorganization were great but rigorous standards were maintained. The new two year predental requirement placed the Columbia dental student on a selective par with the Columbia medical student, the dental students taking their medical subjects in the medical department. In the meantime, the other schools were gradually raising their predental requirements one year to meet the demands of higher education. The privately owned schools were gradually falling into line and at present one of the most interesting experiences in the history of dental education is to be recorded.

The College of Dental and Oral Surgery, a privately controlled institution, has been donated to the Columbia School of Dentistry. Credit for this move must be given to Dean William Carr, which serves as a monument to his unremitting labors in the cause of scientific dentistry extending over a period of thirty years.

Thirty years ago, Dr. Carr was chairman of the law committee of the State society, a body in whose interest he has remained active throughout his entire career. He is credited with being the maker of every dental law, especially those routing out the unqualified practitioner. His education associations began with the old New York College of Dentistry, later with the University of Buffalo, where he remained until he became affiliated with the College of Dental and Oral Surgery.

Only ten years ago the college was housed in makeshift quarters, akin to a barrack, above a penny arcade. Today, entirely through the efforts of Dean Carr, the college is housed in one of the best equipped institutions in the country, with a student body of perhaps eight hundred. It is well to remember that in accepting donations from time to time for the development of the College of Dental and Oral Surgery, Dean Carr long ago made provision for the donation of the institution to a university. His dream is now being realized, for the entire equity of the institution has been turned over to Columbia University for the legal consideration of one dollar.

The educational policy of the new school, to be known as the School of Dental and Oral Surgery of Columbia University, is to be controlled by the administrative board of the Columbia School of Dentistry. No one can fail to appreciate the difficulties attendant upon the administrative board in the new undertaking. The problems are manifold, but it is certain that the administrative board will be able to cope with them. Their sincerity of purpose, their high standards of education, and their cooperative zeal have all been demonstrated in the organization of the Columbia Dental School during the six years of their existence. It is only a question of time when the influence of their cooperative energy will be realized in the professional world, and in the community.

SCIENCE AND RELIGION

There has been a recrudescence recently of the hysterical attack of fright among religionists (religion has had no fear because there was nothing to fear) caused a half century since by the explosion of Darwin's evolutionary bomb. The present unexpected attack seems to have been brought on by a gentleman who "talks much and reads little." But for his unfortunate diarrhea of words the world of the unthinking would have gone peacefully forward. There is, however, a considerable number of scientists who are as nearsighted as the religionists at whom they smile. For these the universe revolves about the "facts" and "laws" laid down by scientists, just as for the very "religious" all things must conform to literal interpretations, according to creed, of the Bible story. A man of far vision among scientific workers is Professor J. S. Haldane and in a recent number of the *Hibbert Journal* he has worded his views of the universe (as well as words will allow, on such a large subject) in masterly fashion.

Speaking of the newer discoveries and generalizations of science he says: "The new knowledge gives a far wider scope to practical philanthropy, but at the same time seems to lead us into materialistic fatalism in which the old spiritual values have disappeared. The universe appears as a material universe which in some mysterious way has become conscious of itself in man and the higher animals, but is otherwise nothing more than a ceaseless and meaningless interaction of atoms and electrons."

"I am convinced that no escape from this conception lies in the direction of denying or doubting the connection between what we call material processes and what we call mental and spiritual phenomena. Nevertheless the conception itself seems to me altogether a false one. The thesis of this article is that the material world which has been taken for a world of blind mechanism is in reality the spiritual world seen very partially and imperfectly, and that the only real world is the spiritual world. . . .

"A living organism is often represented as a structure provided with an immense variety of delicate and extremely efficient mechanisms for preserving itself and its activities from abnormal disturbance or for ensuring their reproduction. This conception, however, is completely inadequate since all the supposed mechanisms are themselves part of what is preserved and reproduced.

"The active persistence observed in the life of the organism can only be the manifestation of a type of order which has not yet appeared to us clearly in what we call the inorganic world. We are therefore bound to believe that, under the guise of mechanically acting forces and random distribution of different kinds of matter, this order must exist in the apparent inorganic world, though we cannot yet see it except with the eye of scientific faith.

"To the materialistic philosophy consciousness is only a byproduct, or accompaniment of some kind, of the material processes in the brain. Plausible though this reasoning may seem to the present generation it makes the gigantic and unwarranted assumption that we really know what 'material processes' are.' . . .

"The reasoning of Berkeley, Hume and Kant throws an entirely new light on our conscious relations to the world of our experience. That world no longer appears as something outside ourselves—an infinity in which we are mere specks. The infinity is within us as a projection of the mind which includes all our experience. Our bodies, regarded as physical bodies, are still mere specks in the physical universe as interpreted in ordinary perception, but the interpreting mind is present everywhere. It cannot be localized in a particular body, since such localization would be meaningless. The visible universe is neither composed of isolated units of matter nor of isolated units of perception. It hangs together as a perceived whole.

"Religion is the recognition in practice as well as in theory of our oneness with God as the ultimate reality. The physical world with its appearance in time and space is, even when with Kant we regard it as a spiritual world of perception, only a very blurred vision of God. We can admire such order as exists in what appears to us the physical world; but in reality chaos and unintelligibility dominate the picture.

"Life and personality appear as miraculous and wholly unintelligible intrusions into it so that it does not hang together. In the world of mere organic life and of individual personality the vision is also a blurred one. We are no mere selfcentred individuals, outside one another, outside Nature and outside God. As individuals we are born and die, and birth and death are neither beginning nor end to real existence. In our oneness with God, but not in the fleeting and unreal appearance of our individual selves, we find immortality and freedom."

DENTAL RADIOGRAPHY

The importance of the radiograph as a diagnostic factor in dentistry is firmly established. The field of its application has been limited until recently, however, to a search for impacted teeth, the location of foreign bodies, the discovery of gross pathological conditions such as cysts, tumors, benign or malignant, and fractures of the maxillæ, and for the verification of a successful completion of root fillings. In short, its diagnostic value concerned gross structural variations rather than detailed structural variation. With the broadening of the diagnostic value of the radiograph, a general misconception ensued in promiscuously designating the presence of unexpected shadowgraphs in alveolar tissues as indicating a pathological condition and attaching a terminology to them not easy to follow on a rational basis.

The dental profession is indebted to Dr. Joseph Pollia, a physician of California, for clarifying the scope and limitations of the x ray as a diagnostic factor in determining the pathological and nonpathological variations of alveolar tissues. A periapical shadowgraph, without the additional clinical evidence, is no longer evidence of a pathological condition. It is merely evidence of a deficiency of calcium content, and, according to Dr. Pollia's findings, a certain percentage of such conditions proved upon careful examination to be sterile.

Dr. Pollia's classifications are valuable and should be sought after by the Life Extension Institute and all others who are engaged in the diagnosis of pathological variations of alveolar tissues. An important asset of the radiograph, as a diagnostic factor, is in relation to detecting the beginning of dental and alveolar pathological variations as an aid to the prevention of dental diseases.

PYLORIC STENOSIS IN NURSLINGS

The symptomatology of congenital hypertrophic stenosis of the pylorus can be stated briefly as follows: In a healthy infant vomiting (geyser vomiting) develops suddenly, and little by little, each nursing is rejected with force. Yet, the infant takes the breast with avidity. Constipation ensues, while exaggerated peristaltic movements from left to right can be seen, the stomach dilates, the urine is scanty, and the infant rapidly becomes emaciated, sometimes losing three or four ounces in twenty-four hours. Radioscopy shows that nothing passes the pylorus and that there is distention of the great tuberosity from air ingested, but no tumor can be detected.

This symptomatology leads one to envisage certain eventualities. In the first place, cardiospasm, spasm of the esophagus or malformations of the tube and subpyloric stenoses must be eliminated. When this has been done there remains the differential diagnosis between true pyloric hypertrophic stenosis and the habitual vomiting of Marfan. There are only three classes of symptoms that can serve in making an early differential diagnosis, the first being that the periods of rest are longer and more plainly manifest in habitual vomiting than in congenital pyloric stenosis. It is true that when the stenosis is not tight, there are phases of relative permeability during which the infant's general condition improves, but these periods are short.

In habitual vomiting, on the contrary, these periods are frequent and long, while constipation is distinctly preceded by a phase of diarrhea. During the evolution of habitual vomiting, the periods of vomiting alternate with periods of enterospasm; when the latter occurs the constipation is replaced by slight diarrhea. This alternating constipation and diarrhea is not met with in pyloric stenosis; it is characteristic of habitual vomiting.

Secondly, one must consider the symptoms indicating the degree of pyloric permeability by means of bismuth and the passage of inert colored substances into the feces. If permeability persists and is not transitory, the diagnosis of pyloric hypertrophic stenosis is practically certain.

Finally, one should observe the effects of diet and medical treatment. Complete failure points to a diagnosis of stenosis, and if after two to three weeks' trial no improvement ensues surgery is indicated.

It is clear that these signs have not an absolute value, but in practice this is of little import, and, what is to be looked for is the indication for surgical intervention. Now, if there is a certain degree of pyloric permeability there is no indication for operation. Radioscopy is of primary importance, as it reveals aerophagy, merycism or enterospasm.

Medical treatment has a diagnostic value as it will relieve the spasm. The number of feedings must be regulated and the important question of the infant's intolerance for the maternal milk—although very infrequent—must not be overlooked. Sodium citrate and bismuth, or a combination of the bromides with belladonna to relieve the spasm, are to be tried. Haas advises freshly prepared atropine in doses of one to two milligrams; the maximum dose being from three to four milligrams up to the age of three months. A one in one thousand solution is used. Begin with one drop at a feeding, then two, so that three to four drops with each feeding are reached in the first twenty-four hours. If at the end of two days there is no improvement, and if there is no sign of intolerance of the drug, it should be pushed so as to reach the daily dose of thirty-five drops. Haas has been successful in numerous cases with this treatment.

Adrenaline, which stimulates the sympathetic nerve ends and is antagonistic to the vagus, has been used; likewise the calcium salts. But as soon as medical treatment shows itself powerless, surgical intervention should be resorted to without further delay.

TONSILLECTOMIES IN ADULTS

It has occasionally occurred to us that a good many tonsils were being removed nowadays for peculiar reasons and with questionable benefit, but we were not quite prepared for the statement made by Walter C. Alvarez in the *Journal of the American Medical Association,* for May 26, 1923, that one out of every four patients who entered his office during the past two years had lost their tonsils. Of the 345 men and women without tonsils who passed through his office 251 had been operated upon during adult life, and he utilized these as material for a study of the reasons why the operations were performed and the results obtained. Although it is not probable that one fourth of our population is tonsilless, it is evident that, if this percentage holds in one doctor's practice, the number of adults on whom tonsillectomy has been performed is sufficiently large for definite conclusions to be drawn as to the conditions under which the operation is advisable. It seems obvious that the general practitioner is in the best position to make the necessary observations, so we commend to him a study of his patients along the lines followed by this writer.

The great benefit obtained from tonsillectomy by all the patients who had been suffering from recurrent attacks of tonsillitis contrasted very strongly with the poor results in 103 patients who had had little or no tonsillitis or sore throat. The figures certainly seem to substantiate Alvarez's contention that it does not pay a patient to have his tonsils removed on general principles, because he is run down or nervous, or because he has headache, deafness, otitis media, enlarged glands in the neck, stomach trouble, or bad breath. He does not stress the point that out of forty-seven who had had their tonsils removed because of rheumatism only seven considered themselves cured and five improved, though it seems worthy of note. But he does emphasize the fact that not one of the thirty-two persons whose tonsils were removed because they were said to be infected was satisfied with the result, and only ten could see any improvement.

Some of the reasons given why the operation was performed are extraordinary. It seems hardly possible that any physician or surgeon can have recommended tonsillectomy as a cure for such diseases as duodenal ulcer, appendicitis, tuberculosis, or acne, yet these are taken at random from the long list of reasons given by the patients why they had submitted to the operation.

Can it be possible that the theory of focal infection has taken such a strong hold upon the imagination of physicians that they are ascribing to it all manner of ills, and are advocating tonsillectomy as a panacea? Possibly, for Alvarez says that, according to his observation, the worst offenders often are physicians who have been cured of some infirmity by the removal of tonsils or teeth and are so impressed that they insist upon their patients submitting to the same therapeusis. The thought occurs to us that possibly the mysticism inherent in the idea of focal infection may play some part, for experience has proved that human nature demands mysticism in medicine. Nothing has ever been propounded so utterly at variance with reason, possibility, or known fact as not to be welcomed as the basis for a new medical departure, and we, although physicians, have a good deal of human nature. We don't understand how a possible focus of infection in an apparently healthy tonsil can make a patient dizzy, insane, or constipated, but, being beyond comprehension, it may be medically right, so, perhaps if we remove the tonsils the patient will get well. The patient's human nature rejoices in the mysticism and accepts the operation.

Tonsillectomy should not be performed on an adult for trivial troubles. Eight per cent. of the 251 patients were made worse, or suffered much for a long while after the operation. It should not be done for relief of troubles elsewhere than in the throat until the patient has been studied carefully by a competent internist. Conservation should be the rule except when there is good reason to believe that the disease can be influenced by the removal of a focal infection, and when there is some reason to thing the focal infection is situated in the tonsil.

RAT PROOF BUILDINGS

An editorial in a recent issue of the Boston Health Department *Bulletin* urges that city to make its buildings rat proof, as a preventive measure against the plague and as an economic necessity. Bubonic plague, formerly known as the black death, is primarily a rat disease, spread to human beings by fleas from sick or dead rats. The only way to eradicate the disease, as has been demonstrated many times, is to stop it among rats, and the only way to do this is to destroy as many rats as possible. To do this, shut off their food supply and deprive them of breeding places and refuges. It has been found necessary at times to rebuild whole cities in order to destroy the rats.

Within a few months after the outbreak of plague in New Orleans, private property owners had been required to pay more than a million dollars to rat proof their buildings. When the plague appeared in Galveston a few years ago, Federal and State officials did not wait for rat proofing by property owners, but demolished buildings and ripped out walls which were harboring rats to such an extent that it was estimated that within a few weeks one twenty-fifth of the entire floor area of the city had been torn away and the owners left to rebuild in a rat proof manner at their own expense.

The article referred to above states that from estimates based on government surveys it may be assumed that there are as many rats in Boston as human beings, and that each rat destroys property annually to the value of about two dollars, which means that it costs about $1,500,000 each year to support Boston's rat population.

As a result of the experience of the world in fighting the plague during the past twenty-five years, the cheapest and most effective way of rat proofing a building of any type of construction has been satisfactorily worked out by the Federal Government. Definite information on the subject will be furnished by the government, but property owners and builders seem to be reluctant to avail themselves of this information. It is also to be remembered that rat proof construction always means increased fire protection for a building and its contents, even if it does not involve actual fire proof construction.

THE DENTAL HYGIENIST

In no part of the body is the need for prophylaxis so great as in the oral cavity. The mouth is the most direct source of infection, where the greatest variety of bacteria can be found. Additional deposits of calcareous substances from the salivary secretions plus the remaining particles of carbohydrate food adhering to the teeth, make the need for oral prophylaxis a most potent factor in the prevention of oral diseases.

It was fitting, therefore, that a special oral hygiene department be organized and that the prophylactic care of the mouth be entrusted to individuals specially trained in the hygiene of the mouth. Such a department was established about seven years ago in Columbia University and is known as the Columbia School of Oral Hygiene. During these seven years some three hundred young women have been graduated as dental hygienists in this city. At the same time schools have been started in Rochester, N. Y., and in Boston, which are splendidly equipped to carry on the campaign for preventive dentistry.

At present the services of the dental hygienist are being utilized in some dental offices, in certain industrial institutions where employees are cared for, in many orphanages, and, in conjunction with the department of health, in a few selected public schools. Unfortunately, the number of dental hygienists is still inadequate, but it is to be hoped that the authorities will make provision for supplying all public schools with dental hygienists. Their services are invaluable, especially in schools, where the groundwork for preventive dentistry should be laid.

News Items.

Dr. Joseph F. Montague Elected to Office.—Dr. Joseph F. Montague was elected to the office of secretary-treasurer of the American Proctological Society at their annual session in Los Angeles.

Dr. Norris Sails.—Dr. Charles Norris has sailed for a vacation in Europe. Dr. Norris will tour Austria, Italy, France and Switzerland and at the same time will study foreign methods of handling the problems with which he is confronted in his duties as Chief Medical Examiner of New York. He will return September 16th.

Dr. Blanche N. Ehler Appointment.—Dr. Blanche N. Ehler, of Hatteras, N. C., has been appointed by the United States Public Health Service to furnish professional services to Coast Guard Stations Nos. 181 to 185. She will also examine candidates who apply for admission to the Coast Guard service at stations under her medical supervision.

Dr. Leland E. Cofer Appointed.—State Industrial Commissioner Bernard L. Shientag has announced the appointment of Dr. Leland E. Cofer, of New York, as director of the Division of Industrial Hygiene of the State Department of Labor. Dr. Cofer has been an officer in the United States Public Health Service for over thirty years .

Dr. Flexner Appointed Health Council Head.—Governor Smith has announced the appointment of Dr. Simon Flexner, of New York, as chairman of the public health council, to fill the vacancy cansed by the death of Dr. Hermann M. Biggs, formerly State health commissioner. Dr. Flexner is director of the Rockefeller Institute for Medical Research.

Vital Statistics for Massachusetts.—Statistics show an increase in deaths and a decrease in marriages and births in Massachusetts during the past year. Last year there were 87,636 births, or 22.3 in a thousand of population, as compared with 92,207, or 23.7 in a thousand in 1921. Marriages numbered 32,683 in 1922 and 33,590 in 1921. Deaths were 51,115, or 13 in a thousand, in 1922, and 47,780, or 12.3 in a thousand, in 1921.

Dr. Hunt Heads Tuberculosis Division in Veterans' Bureau.—Dr. James P. Hunt, of 58 West Fifty-third Street, Manhattan, has been appointed head of the tuberculosis division of the veterans' bureau, succeeding Dr. Stanley M. Rinehart, who resigned to accompany his wife, Mrs. Mary Roberts Rinehart, to their ranch in the West. Dr. Hunt was formerly attached to Bellevue Hospital and also to the New York office of the Veterans' Bureau.

Dr. Nicoll Health Chief.—Dr. Matthias Nicoll, Jr., of Albany, has been appointed by Governor Smith, State Commissioner of Health, to succeed the late Dr. Hermann M. Biggs, who had held the post since 1914. Dr. Nicoll has been with the department for the past eight years and for the past four years has been deputy commissioner. Prior to that time he was secretary of the department and director of public health education. Before he came to Albany he was associated with Dr. Biggs and Dr. William H. Park in public health and laboratory work in the Department of Health of the City of New York.

Dr. L. Miller Kahn Appointment.—Dr. L. Miller Kahn has been appointed attending surgeon to the Beth David Hospital.

Industrial Accidents Increase.—According to statistics compiled by the Department of Labor and Industry, Harrisburg, Pa., industrial accidents for the last six months totaled 100,421, the highest postwar casualty record. A slight decrease in fatalities for June was reported.

Influenza Ravages Chile.– Santiago is in the grip of an influenza epidemic. More than 100,000 cases have been reported, most of them among the poorer inhabitants. The extremely cold winter is believed to be aggravating the situation.

Governor Breaks Ground for Hospital.—Governor Alfred E. Smith broke ground for the new Veterans' Memorial Hospital at Kings Park, L. I., near the State Hospital for the Insane. The buildings when completed will cost $1,500,000 and will house at least 1,000 of the 1,400 insane veterans in New York State. Funds for the hospital were appropriated after Governor Smith had sent a special bill to the legislature.

Turks to Have Their Teeth Filled.—A decree has just been issued by the Department of Religious Affairs permitting the Turks to have their teeth filled. Although, of course, the educated Turks for many years past have had dental treatment when necessary, the peasants of Anatolia, rather than transgress the law often allowed their teeth to become hopelessly decayed and contented themselves with having the most troublesome teeth pulled.

Cornell Scholarship Award.—A travelling fellowship in medicine has been established at the Cornell University Medical College for 1923-1924 amounting to $2,000. It is available for men and women who have graduated from Cornell within ten years or who are graduates of other medical colleges within ten years but who are now attached to the instructing staff of Cornell. Candidates must have completed a hospital internship or have engaged in laboratory training or research for two years after graduation. This year's fellowship has been awarded to Harold Edwin Himwich who obtained the degree of B. S. from the College of the City of New York in 1915 and an M. D. degree from Cornell University in 1919. Since that time Dr. Himwich has been an interne at Bellevue.

Notice of Postponement.—The Committee of British Ophthalmologists appointed to organize an International Congress in 1925 announces that it is unable to do so in accordance with the conditions under which the British invitation was accepted by the Washington Ophthalmological Congress in 1922. At Washington it was decided that the next Congress should be strictly international and that German should be one of the official languages. The committee has since been informed that the Société Française d'Ophtalmologie, the Société d'Ophtalmologie de Paris and the Société Belge d'Ophtalmologie have passed resolutions to the effect that they feel themselves unable to participate in a congress if Germans are invited. The committee believes that to proceed with the congress in these circumstances would tend to perpetuate a schism in the ranks of ophthalmology and therefore decided to postpone the congress.

LATIN AMERICA LETTER.

(*From our own correspondent*).

Balboa Heights, *May 20, 1923.*

AMERICANS IN THE TROPICS.

Every year there is an increasing tide of American travel to the tropics, particularly to Central and South America. A considerable proportion of this is along the beaten tourist routes and involves about as much of a health hazard as a trip to a Sunday School convention at Sioux City. The balance represents a definite emigration for the purpose of engaging in diplomacy, engineering, medicine, trade and land development, and to this group there may be an actual menace. To be sure, the American Minister at, let us say, Panama is just as safe as he would be in Paris, because every sanitary precaution has been taken for him by the health authorities, and life differs really very little from what it is at home. On the other hand, the engineer or physician who is out on an oil development project in Venezuela must rely on his own intelligent effort, and if he is ignorant of the basic principles of maintaining health, he is apt to be recruited to that vast army of Nordics who perpetuate the ancient superstition that the blond white man is not adapted to life in warm climates. This applies with even greater force to those transplanted American women who persist in taking their daily dozen, in the hammock or at the bridge table, and to whom a freckle is about as welcome as leprosy.

DEGENERATING EFFECT OF LIFE IN THE TROPICS.

There is a widespread belief, even among medical men, that there is something about life between 23½° N. and 23½° S. which rapidly undermines the health of all white people, except those from the Mediterranean basin. A moral, dispositional and physical retrogression is supposed to result from its malign influence, and neurasthenia, hypochondriasis, and insanity are supposed to follow in its train. Even many tropical dwellers harbor this weird belief and explain the results of overdrinking, overeating, underexercising, and the violation of the most fundamental rules of personal hygiene by the trite phrase, "He has missed too many boats." Continuous high temperatures, white light, humidity, and the combination of all three, have been blamed, yet, strangely enough, the baleful symptoms of this mysterious ailment are observed in dry and humid, bright and cloudy climates, on mountains and at sea level, in cool and hot tropics alike; and, still more strangely, there are many Americans who have resided for many years in Central and South America without undergoing physical, mental or moral deterioration. They are the Nordics who have adjusted themselves to the new environment and the boredom of a climate with relatively little seasonal change, who have had the courage and the initiative to resist the slump which so frequently follows isolation from one's own kind. It must be admitted that there is a dangerous lassitude about warm countries. It is so easy to omit shaving in the morning or to slouch around the house in a "mother hubbard;" in a country where few wear shoes "and restaurant waiters strut about with shirt-tails out behind," the lowering of one's standards is not difficult. The Englishman learned this long ago and when he moves to the tropics, he takes a little bit of Merrie England with him and clings doggedly to his customs and conventionalities for the salvation and protection of his soul and body. The fact is, that people of the same general habits have about the same degree of health, no matter what their exact geographical position may be, and that every infraction of the laws of health is punished, no matter where committed. To be sure, one does not dress, eat and exercise in exactly the same way in Curacao as in Chicago, any more than one would follow the same regimen of life in Memphis and Moscow, but, leaving out of question the communicable diseases, personal health is largely a matter of character and intelligence, that is to say, of cleanliness, diet and exercise.

PERSONAL CLEANLINESS.

Personal cleanliness is even more necessary than in temperate climates, if one is to avoid skin infections. In the humid tropics thorough soap and water baths should be taken at least daily. Some skins require the application of a little fresh coconut oil after bathing. The hair must be washed frequently and it is wise to practice axillary shaving. The various forms of ringworm and other skin parasites are very prevalent and every wise white man living in the moist tropics keeps a little tin of dhobie itch ointment on hand ready to apply at the first indication of skin infection. Except in the very dry tropics, it is always possible to take a bath. Shower baths may be rigged out of perforated oil tins and in temporary locations, a native may always be secured to pour water over the bather from a height. Towels and washcloths should be sterile. This is important and is not difficult to achieve if care is taken that the lavendera dries them on a line or a sheet of corrugated iron in the broiling sun. They should never be dried on the earth or grass. After the bath, clean clothing should be put on from the skin out. This requires a fairly large wardrobe of underwear, stockings, shirts and suits or dresses and naturally entails considerable laundry work. The latter is not expensive and the outlay for clothing not as great as in the United States, e. g., the laundry work for a family of two will cost from three to twelve dollars gold a month, varying with location, and three export flour sacks, which may be purchased for twenty-five cents each, may be made into a very serviceable and good looking suit of clothes by a native tailor for eight dollars.

CLOTHING TO BE WORN IN TROPICAL COUNTRIES.

The kind of clothing to be worn naturally depends upon the climate and here it is wise to conform to local customs. In the warm tropics the basic idea to be followed is that of bodily ventilation and sun and weather protection. Underwear, stockings and shoes, both whites and leather, are better brought from home. Wash clothes can be secured more cheaply locally. For rough work in the jungle, breeches and boots or high shoes and snug puttees are necessary for protection against ticks and the like. The bare foot should never be set upon the ground, in fact, the danger of contracting hookworm infection is so great that, even in the house, shoes or native slippers like the hempsoled alpargata should always be worn. For headgear, the Panama hat is light and comfortable. In purchasing, one should always hold the hat to the light to see if it leaks light and count the rings in the crown and examine the edge to determine the quality. For the wet season the Army Stetson is admirable. A good many Americans have a prejudice against the helmet but it really is an excellent piece of headgear, the pith or semicork variety affording sun protection and the ones of rubber composition shedding water well.

DIET.

Diet is largely a matter of personal taste but, as a rule, it is wise to study the local dietary carefully and adapt it to the American palate. The housewife who is hidebound and insists on serving the menu which was the rule in the particular Mink Centre from which she originated is taking dangerous liberties with the digestions of her family. She must do her own marketing and she must learn to avoid the tin can, smoked meat, sausage, crackers and cheese diet which has driven many a good husband to the cantina. Equally she must busy herself with the native cook lest she serve greasy red beans and rice, garlic and stew with frightful and odoriferous monotony. The newcomer is pretty apt to have a preliminary stimulation of the appetite and digestive functions but this soon passes and the taste for food and the powers of assimilation are lowered. This and the failure to eat sufficient roughage may explain why spices and cathartics are used so much more than at home. The diet must be well balanced. At first there is the temptation to overindulge in the fruits and carbohydrates. The candy box, the rich after dinner *dulce* and the starchy yam or yuca, all contribute to the carbohydrate poisoning which is so common in the tropics. An excessive meat diet is apt to cause a putrefactive process in the intestinal canal and thus produce toxemia and chronic ill health. The menu must be varied. After the stomach has been offended day after day by the same old tinned asparagus and the inevitable canned peach, it is rather likely to put on its war bonnet, leave the reservation, and begin the slaughter of the settlers.

ALCOHOL IN THE TROPICS.

Alcohol must be taken only in extreme moderation, and in the absence of daily exercise, never. Better still, it is best left strictly alone. The tropical steady drinker who does not exercise breaks up quickly. There is a certain lack of selfrestraint which characterizes all frontier places, especially the tropics, and thoughtless men and women let loose from the restrictions of the home environment sometimes do themselves great harm. Alcohol, slothfulness, and the lowering of personal standards are more responsible for the breakdowns which are commonly attributed to a tropical climate than any other combination of forces, with the possible exception of malaria. Unfortunately a good many North Americans are not as temperate as the representatives of a prohibition nation should be and they drink in a way which is harmful to themselves and shocking to the Latin Americans. They do themselves no good by their intemperance and they bring upon the nation the hurtful reproach that its citizens do not obey the spirit of their own laws. Occasionally in situations in which the water is bad, one must drink beer or wine or run the risk of contracting typhoid fever or dysentery, but usually safe bottled water can be obtained if one but looks for it.

EXERCISE.

Exercise in the open air is even more necessary in the tropics than in the temperate zone. The daily siesta, the easy chair, and the avoidance of walking are deadly in warm countries and a great many of the socalled tropical neurasthenias are largely the result of physical laziness. This is particularly true of women. Conversely, tennis and golf, particularly the latter, are tremendous health adjuvants in warm countries. Swimming, fishing, hunting, riding, and exploring, in fact anything which will get people to exercise in the open air, go a long ways to prevent those mental quirks which inevitably arise when a small isolated community of Nordics are absolutely dependent upon one another's society. The untanned man or woman in the tropics is headed for physical and perhaps moral disaster, and this is the more inexcusable in a climate where out of door exercise is pleasant the year around, where there are orchids and strange flowers to gather, ancient ruins to study and adventurous roads to travel.

VENTILATION AND PROTECTION AGAINST INSECTS.

Indoor comfort is largely a matter of ventilation and protection against insects. The house must be open to every breeze that blows yet it must be shaded but not too dark, and it must be kept absolutely clean. During the wet season clothing will mold easily unless kept in a dry closet. Even then it is wise to get things out into the sunshine every day or two. A good sized piece of camphor gum exposed in the closet helps to keep down mold. Good wire screening is a necessity, if one is to avoid man's ancient enemy, malaria, and there must be an unending warfare against ants and cockroaches. The house must be rat proof and rat free if one would keep plague away and there must be no mosquitoes breeding on the premises. Flies, of course, must be excluded, and the grounds surrounding the house kept clean. In selfdefense it is frequently necessary to take an active interest in the sanitation of the entire district or town and it is surprising how much a little intelligent effort will accomplish in improving the sanitation of a tropical environment. An American at San Juan del Sur, Nicaragua, drained the town and got rid of malaria, took the pigs off the streets and put them in clean rat proof pens and got rid of flies, beautified a public plaza and thus stimulated civic pride, all for less than a thousand dollars. An American consul at an important Central American seaport so stimulated public opinion that an efficient, full time sanitary inspector was employed, the garbage disposal, conservancy and streetcleaning of the town were improved, mosquito larva destroying minnows were maintained in all water containers, and what had previously been a most insanitary place was transformed into a safe and comfortable spot in which to dwell.

PROPHYLAXIS AGAINST TROPICAL DISEASES.

The person who sets out for the tropics without being protected against smallpox, typhoid and paratyphoid fevers and dysentery is assuming an unnecessary and very genuine risk. Smallpox is generally very mild among the native population which regards the disease with apathetic fatalism. Many of the larger cities have sewage and water mains which intercommunicate and their morbidity and mortality rates for the intestinal diseases are very high. Families resident therein are obliged to boil all drinking water. The stone filters so frequently seen in such places are an abomination and are only mentioned to be condemned.

ADAPTATION TO CONDITIONS.

After all, the Nordic who goes to the tropics must adapt himself to his new environment in exactly the same way that he would anywhere else in the world. He can do this if he will assume an intelligent forceful attitude, if he will take as many precautions to maintain his health as he would in any other place of the same sanitary condition. At first he will miss the stimulation of the society of people having the same hygienic ideals as he has, but if he is a person of character, he will not lower his standards and he will realize that by living up to them he may keep well in body, mind and soul. If he is a physical, mental or moral weakling, he had better never leave the sheltered environment of home. Such a person is pretty apt to get into harmful habits, to degenerate into the all too common beachcomber, and to become a disgrace to his race and country. If he is narrow and chauvinistic, or if he is that obnoxious type of American who is always telling people how much better we do things, he may be safe in health but he certainly will not add to the prestige of our country. The tropics need active, keen witted Nordics of character who can resist temptation and will keep themselves physically fit. For such there are ample rewards because they can adapt themselves to any environment, be it tropical or polar, but for the weak, the slothful, the stupid and the ignorant, failure is foredoomed.

PLAGUE PREVENTION MEASURES.

The Health Department of the Panama Canal is greatly concerned lest plague be introduced into Panama, the widespread prevalence of that disease in the seaports of the world making such a contingency possible unless every precaution be taken to prevent the introduction and breeding of rodents. A recent inspection of various storehouses in Panama City showed evidence of a large number of rats therein, and a circular has been issued outlining the plague preventive measures which will be put in force and requesting the cooperation of all residents in the expedition of this important work. All buildings undering repairs must be rat proofed in accordance with the sanitary regulations. In storehouses, warehouses, yards, patios, etc., that are used for storage purposes, all stored materials, foods and merchandise, boxes, barrels, crates, etc., must be placed on racks elevated from the floor at least eighteen inches and not over six feet in width. These racks must not be nearer one another than two feet and the spaces between them must be kept clear of material of every kind in order to make easier their inspection and the trapping of rats. The rat guarding of ships is being carefully continued and vessels are required to undergo fumigation prior to entering the drydock.

PERSONALS.

Dr. W. E. Deeks, of New York, the general manager of the medical division of the United Fruit Company, and Dr. Hunt, the president of the Island Medical Board of Jamaica, recently visited the Isthmus on a tour of inspection of the various ports of Central America and the northeast coast of South America. Dr. Deeks was for many years the chief of medical clinic of Ancon Hospital and several of his former coworkers gave a banquet in honor of him and Dr. Hunt at the Union Club of Panama, Dr. William James serving as toastmaster. *Hubo múltiplés Brindas.*

LONDON LETTER

(From our own correspondent)

London, *May 5, 1923.*

ENCEPHALITIS LETHARGICA.

The Medical Congress held recently in Vienna was productive of some valuable discussions. Perhaps the most remarkable report delivered was that of Professor Economo on encephalitis lethargica, termed in this country sleeping sickness and in Austria influenza of the head. As is well known, this disease was very prevalent in Europe during the war. As for its etiology, according to Economo, investigations showed the presence of certain bacteria in the brain; Doerr and Levaditi found that these bacteria were filterable and transmissible to the cornea of rabbits, where they produced symptoms similar to those obtained by infection with the contents of the ordinary herpes vesicles. It seemed likely that the etiology of herpes and that of encephalitis lethargica were identical, but in the latter disease the virulence was much greater for reasons still unknown. Transmission probably took place through the air, by way of the nasopharynx. A few contacts were infectious. Treatment against the encephalitic processes could be satisfactory in the early stages only. Intravenous infections of large doses of iodine gave good results in acute cases; chronic cases were still resistant to treatment. Between forty and fifty per cent. of patients die; and even in cases of recovery it was questionable whether the disease would not become chronic. The effects of this disease are of great interest to nerve specialists, as changes in personality, states of apathy, or, on the contrary, an intense desire for activity, are characteristic features of the condition.

Prof. M. Nonne, of Hamburg, read a second paper on this subject. He dealt chiefly with the clinical picture of the disease. While agreeing with Professor Economo with respect to the etiological factor, he suggested the possibility of a special neurotrophic toxin, similar to that found in metasyphilitic processes. The manifestations of chronic encephalitis could be placed in three groups: In the first, psychic symptoms were prevalent; in the second, the disturbances were centred in the organs of movement; and in the third, metabolism was chiefly affected. Often nothing was observed but a change in personality, without marked intellectual difference. The study of the pathology of this disease had greatly influenced current views as regards the diseases of the nervous system; it had given useful clues as to the function of the nucleus caudatus and nucleus lenticulatus, parts of the brain which controlled the voluntary innervation of single groups of muscles.

MENTAL SICKNESS.

According to a statement made by the medical correspondent of the London *Times* in a recent issue, Lord Onslow has introduced a bill into the British Parliament which aims at far reaching changes in the present system of dealing with insane persons and which makes provision for the temporary treatment of mental disorder without certification. It is laid down that local authorities may appoint as members of visiting committees persons who are not members of the council of the authority and that two at least of the members of every visiting committee shall be women. Subject to certain consents a visiting committee shall have the power to make agreements with other visiting committees, providing for joint exercise of powers; it shall be also able to provide or arrange for outpatient treatment of persons suffering from mental disorders, and to take as boarders voluntary patients who apply in writing, in the case of those under age, application to be made by parent or guardian. The committee is further empowered to make provision for the aftercare of persons discharged from mental hospitals and to undertake, subject to the approval of the board of control, research work in mental diseases. Regulations governing the acceptance without certification of patients likely to benefit by temporary treatment in an institution are a prominent feature of the bill. The period of such acceptance without a receiving order is fixed at six months, but may be extended to a year.

Recommendations for treatment shall not be given, however, except in respect of a person who either is willing to submit to treatment, or is incapable of volition, or in whose case, if he is a minor, consent has been given by parent or guardian. Every application must state under which of these categories the patient comes. The board of control is given powers to "approve" unregistered hospitals, or any part of them for the purposes of this treatment, which may also be given in any registered hospital, institution or licensed house, under the control of a visiting committee. Recommendations for treatment must be given by two medical practitioners, of whom one shall be a person approved by the board or the local authority. Persons received for treatment as boarders or patients may, 1, leave at any time after giving forty-eight hours' notice; or 2, be discharged by the medical superintendent or by order of a commissioner or by any person who would be entitled to direct his discharge if he were a private patient detained in an institution for lunatics. In the case of a minor, notice of intention to leave shall be given by parent or guardian. This new departure in the methods of treating the mentally sick is in keeping with the most recent conception of mental disorder, that is, treatment by specialists in the early stages so as to prevent the disorder from developing. Up to the present the laws regulating the treatment and control of lunatics were such that no special treatment was available for those with moderate means, except they allowed themselves or their parents or guardians allowed them to be incarcerated in a lunatic asylum. If the bill passes a new era in the treatment of the mentally sick in Great Britain will set in.

PANEL DOCTORS' PAY.

The annual conference of the Association of Approved Societies has just been held, when the question of the remuneration of medical men practising under the insurance act was discussed. The chairman said there had been talk of a doctors' strike, though the doctors resented the word strike. The doctors on the whole had rendered wholehearted service, but there was also a good deal of nonsense talked about doctors' selfsacrifice. Doctors were not the only selfsacrificing profession. They, like others, had adopted their profession to obtain a livelihood. They had a right to combine to get results, but those who were to pay the doctors were also entitled to be consulted with regard to the terms. Approved societies had considered the question of extending the medical service and Sir Alfred Mond, the late Minister of Health, had lent his weight to the idea, put forward some years ago, that medical service should be reorganized on a family basis. This had been described as a state medical service. If they had to pay anything like the sum the doctors desired, they might as well go the whole length and pay for state medical service. The matter of medical men's service under the insurance act seems as if it were approaching a crisis. The Approved Societies, who have contributed towards the remuneration of the medical men, do not appear to be inclined to continue to do so unless they are given a dominant voice as to the manner in which the medical men should conduct their practice. Probably the question will be threshed out before long.

DEATH OF SIR SHIRLEY MURPHY.

A great public health officer, a pioneer in some directions, passed away on April 27th last, full of years and honors. Shirley Foster Murphy was born on May 21, 1848, in London. He was educated at University College School and Guy's Hospital. His medical interests were confined mainly to epidemiology and prevention and after a good deal of experience of these questions he obtained the appointment of medical officer of health of St. Pancras, one of the largest of the London boroughs. Reactionary opposition was so strong that Murphy, despairing of making progress, resigned in 1884 and adopted the bold policy of setting up as a consultant in public health, in the quarter of London in which specialists mostly congregate. When the London County Council was formed Murphy secured the appointment under this body of the first medical officer of health of the County of London, which he held for twenty-two years. In this position Murphy did great work, aided by his able staff, and especially by Dr. Hamer and Dr. Young. A knighthood was conferred upon him in 1904, the Royal College of Surgeons granted him the honorary fellowship and the Royal College of Physicians the Bissett Hawkins medal in 1908. He retired in 1911. As soon as war broke out he volunteered for duty, was made a Lieut. Colonel R. A. M. C., on the Territorial list for special sanitary service, and was attached to the London Command. In 1919, in recognition of these services, he was created K. B. E., and in the same year represented the British Government at the congresses of the American Medical Association and the Ontario Medical Association. In 1921 he was nominated by the Minister of Health as one of the managers of the Metropolitan Asylum Board. Although of a shy and retiring disposition he had many friends in almost all classes of society. Among many other distinctions he was awarded the Jenner medal by the Royal Society of Medicine.

Book Reviews

DENTAL RADIOGRAMS

Dental and Oral Radiography. By JAMES DAVID MCCOY, M.S., D.D.S., F.A.C.D. With 116 illustrations. Third Edition. St. Louis: C. V. Mosby Company, 1922.

Dr. McCoy includes in his textbook a consideration of both the technical aspects that enter into the production of the radiogram and the diagnostic value or interpretive aspects. The material is well grounded and well ordered and should serve the purpose intended by the author, namely, to produce a textbook for students and practitioners. Dr. McCoy would have been interested in the new technic for controlling the central ray in a predetermined angulation, as outlined by Dr. J. F. Freund in this issue of the NEW YORK MEDICAL JOURNAL.

The author utters a proper word of caution concerning the use of the radiograph only as a diagnostic aid in connection with clinical evidence.

ULTRAVIOLET RAYS IN DENTISTRY

Ultraviolet Energy in Dentistry. By A. J. PACINI. Chicago: Victor X Ray Corporation, 1923.

According to Dr. Pacini abscesses, acute and chronic, antrum empyema, caries, fistulæ, fractures, gingivitis, cellulitis, necrosis, and osteomyelitis can be cured by the use of ultraviolet energy. The pathological conditions mentioned above are only a few of those enumerated by Dr. Pacini. Curiously enough he promises no cure for pyorrhea alveolaris, nor does he assure the sterilization of root canals with ultraviolet energy. It is also interesting to note that the use of this energy is suggested only as an adjunct to surgical procedures. We wonder whether Dr. Pacini is aware that what he is actually contending is that the ultraviolet energy should be used only when and where surgical intervention has already effected a cure.

THE BUCCAL CAVITY

Diseases of the Gums and Oral Mucous Membrane. By Sir Kenneth Goadby, K.B.E., M.R.C.S., L.R.C.P., D.P.H. London: Henry Frowde and Hodder & Stoughton, 1923.

The literature regarding clinical pathology of the tissues within the buccal cavity has been scanty and unorganized. Within the last year two books have made their appearance. Stillman and McCall's *Clinical Periodontia* was reviewed in these columns some time ago. This book dealt largely with diseases of the tissues surrounding the teeth, the etiology of which was local. The scope of Goadby's work is much broader. The book may be divided into two sections: the pathology of oral tissues of local origin, and the pathology of oral tissues incident to and symptomatic of systemic disease.

Little variance can be noted in the handling of the same subject by the two authors. Both are keen observers, and Sir Kenneth, like Dr. Stillman, takes exception to the use of the term pyorrhea alveolaris to designate a disease of many stages ranging in its incipiency from a mild gingivitis to the production of pus only in its late or final stages. The second part of the book, dealing with the pathology of the tissues in the buccal cavity incident to and symptomatic of systemic disease, is especially interesting to the members of the dental profession. It offers a splendid opportunity to become familiar with the clinical evidences of diseases such as syphilis, as an aid to diagnosis. The book is scholarly throughout and detailed in its descriptions. There are occasional colored plates—all intended to portray vividly the clinical picture of the disease to the general practitioner. The publishers deserve a word of praise for the production of this book.

DISEASES OF THE DIGESTIVE TRACT

Krankheiten des Verdsunngskanals (Oesophagus, Magen, Darm). Von Dr. Paul Cohnheim. Berlin: Verlag von S. Karger, 1923.

The fourth edition of Cohnheim's excellent monograph on diseases of the digestive tract is both precise and practical. In the treatment of appendicitis Cohnheim advises the following: Treat conservatively, i. e., medically, typhlitis and simple appendicitis; operate in the acute stage in perforation and gangrenous appendicitis; operate in the interval in recurrent appendicitis and in appendicitis lavata (Ewald), if there are sufficient symptoms to justify such a procedure.

The diagnosis of intestinal ulcers is based on the presence of pus and small particles of tissue (mucosa) in the stool. Blood in the stool is also of importance. Watery evacuations, however, are not sufficient for the diagnosis of intestinal ulcers. In an acute attack of diarrhea Cohnheim recommends calomel, four grains, two doses in an interval of two hours; two hours later give a dose of castor oil. For a few days, give the patient no nourishment except weak tea. Opium should not be given.

ANESTHESIA

Anesthetics in Practice and Theory. A Textbook for Practitioners and Students. By J. Blomfield, O.B.E., M.D. (Cantab.) Chicago: Chicago Medical Book Co., 1923.

This eminently practical book deserves a welcome in spite of the fact that numerous books on the subject have been published recently. It is a valuable aid to any one who desires to perfect himself in the science and art of anesthesia. Adequate attention is given to both experimental and practical (physiological and surgical) aspects of the subject. The author emphasizes the fact that the anesthetic and the method of its administration must be suited to the individual patient, to his disease, and to the type of the operation perfomed. The physical and chemical nature and the physiological action of general anesthetics are discussed.

A special chapter is devoted to those anesthetics that are less commonly used, such as amylene, pental, amyl chloride, butyl chloride, bromoform, carbon dioxide, carbon tetrachloride, chloral, ethyl bromide, ethidene dichloride, hedonal, hydramyle, isopral, methyl oxide, magnesium sulphate, nitrogen, hypnotism, hypnonarcosis, acetone, benzene, ethyl nitrate and turpentine and the electric current. On the whole, chloroform is looked upon with ill favor in America, but the author, as do most European anesthetists, believes that chloroform still deserves to be used in certain cases, particularly the chloroform ether mixture. The various anesthesia apparatus, all of the English type, are accurately described. The preliminary use of narcotics is given full consideration. The etiology and treatment of undesirable conditions, accidents and complications arising during and after anesthesia are studied.

The unusual uses of anesthesia is a subject usually not given consideration in textbooks but is given ample consideration here. The various technics and solutions used in local analgesia are also included, as well as the subjects of spinal and sacral analgesia. A special chapter is devoted to the fatalities of anesthesia. Anesthesia in obstetrics, including the subject of hypnosis is discussed. The citations from the literature are numerous and quite recent and give due credit to American and Continental authors. This book is a valuable addition to the literature on anesthesia.

THE TUBERCULOSIS WORKER

The Tuberculosis Worker. A Handbook on Methods and Programs of Tuberculosis Work. By Philip P. Jacobs, Ph.D. Baltimore: Williams & Wilkins Company, 1923.

This is a unique book, perhaps the first one of its kind in existence, written by a man who, as a layman, has doubtless had a larger experience with tuberculosis as a social disease than any other man. Although the book contains only about three hundred pages, it contains a vast amount of information essential to all who would wish to be efficient in the solution of the many problems which confront the layman or woman who has joined the ranks of tuberculosis workers.

To give a fair idea of the interesting way in which the subject is presented, it may be well to enumerate the nineteen chapters of Part One, in which the respective subjects are treated with brevity and clarity: 1, The health salesman; 2, exhibits; 3, newspaper publicity; 4, the printed word; 5, the modern health crusade; 6, the spoken word; 7, motion pictures; 8, other educational methods; 9, organization methods; 10, clinical methods; 11, medical service; 12, nursing methods; 13, industrial methods; 14, open air schools and preventoria; 15, institutional methods; 16, survey and statistical methods; 17, financial methods; 18, financial methods concluded; 19, cooperation with public officials.

In chapter I the author defines the tuberculosis secretary as one who is in a real sense a salesman, who goes into the community and seeks to arouse a sufficient amount of interest and enthusiasm to secure the necessary machinery for the control of tuberculosis. The machinery consists of men, women, children, institutions, and money. To get these he must sell an idea, namely, that health is a profitable and paying individual and community investment. I am sure that under men and women the author includes the physicians of both sexes, although he fails to emphasize this point.

In chapter VIII, under the heading Other Educational Health Methods, Dr. Jacobs mentions the experience with the health clown, which proved so efficient in interesting school children in health methods, and describes parades, baseball games, pageants and plays, marionettes and toy theatres as helpful in arousing the interest of adults and children and urge them to coöperate. Most instructive is chapter XIV, devoted to open air schools and preventoria. In this chapter it is interesting to note the divisions of open air schools into three kinds; first, the school for the typical tuberculous child; second, for the predisposed or pretuberculous child; and lastly, for the normal child. The selection of cases for such schools and their equipments is dealt with in detail. Equally instructive is the succeeding chapter on institutional methods which deals with the planning of special hospitals and sanatoria. Under Cooperation with Public Officials it is emphatically stated that the campaign against tuberculosis is part of the great public health movement and should always be so considered. The broader campaign implies a recognition of the official aspects of community life as well as of the unofficial aspects. It implies further, that the tuberculosis movement must of necessity coöperate with public agencies—city, county, state, and federal.

Part Two of the book is devoted to methods in their definite relation to programs for local, state, and national work. These programs give an excellent idea how urban, rural and state committees should proceed in their antituberculosis campaign. The celebrated Framingham program is given in full and for its well known results it deserves the widest emulation. Each of the twenty-six chapters of the book is followed by selected references to articles, constituting a veritable bibliography which may be consulted for additional information. Thus the volume offers not only to the lay workers but also to the physicians interested in the tuberculosis problem a mine of information difficult to obtain elsewhere. The author is to be congratulated on having accomplished a difficult task and on presenting so useful a book to medical and lay workers for their guidance in carrying the prevention of tuberculosis to the people. Dr. Jacobs's book will be one of the most effectual means to bring about an ultimate eradication of tuberculosis as a disease of the masses. It should be in the hands of every one interested in the solution of the tuberculosis problem and the health and welfare of the people at large.

FRACTURES AND DISEASED JOINTS

The Ambulatory Treatment of Fractures and Diseased Joints. By C. A. Hoefftcke. With an Introduction by Frank Romer, M.R.C.S., L.R.C.P., and articles by many Eminent Surgeons and Physicians. With numerous Illustrations. London: William Heinemann, Ltd., 1923.

Views as to the most effective mode of treating fractures and diseased joints have changed greatly within recent years. It used to be an article of faith with surgeons and medical men generally that complete rest was the essential treatment in such cases, and to advocate movement, at any rate in the early stage, would be sinning against the laws of nature. The great British surgeon Hugh Owen Thomas in 1878 laughed to scorn the extension principle which, by the way, was introduced and employed in America, to some extent, before 1878, and Hoefftcke's ambulatory extension splints have been used in Great Britain during the past twenty years for diseases of the joints and fractures. One of the essential points concerning which the experiences of the recent war have apparently resulted in a more or less complete agreement, is the rule that continuous extension, in a general way, is to be preferred to immobilization. In fact, this was one of the chief lessons learned in the war.

Willems, the well known Belgian surgeon, was the most enthusiastic exponent and protagonist of treatment by spontaneous immobilization of suppurating joints and it may be stated without exaggeration that the results have marked a new epoch in treatment. Not only Willems, but surgeons and general practitioners of every nationality, have become convinced of the ill effects of long continued immobilization and many who have practised this method of treatment for years have seen fit to revise their opinions. As Mr. Frank Romer says in the introduction to the book which is being discussed, "It would appear, as Sir Arbuthnot Lane points out, that provided the articular surfaces are prevented from impacting forcibly on one another by sufficient extension, that many diseased joints can be safely and advantageously kept in functional use," and this statement expresses the views of authorities on the subject everywhere. For this purpose Hoefftcke's splint is specially designed and the list of cases enumerated in the book seem amply to demonstrate its value.

Moreover, it is stated that this form of treatment has been followed by great success in cases of arthritic origin, a type of disease unduly prevalent at the present time, which, as well as being one of the most painful and crippling diseases known, is one of the most difficult to relieve or treat successfully in any way.

Mr. Hoefftcke's book provides a full and clear description of his methods of treatment and of the appliances by which this treatment is carried out, while the use of the appliances is explained or rendered more easy of comprehension by means of a large number of graphic illustrations. Many of the best known surgeons of Great Britain have written favorably of Hoefftcke's methods and John Fairbairn Binnie, of Kansas City, in his treatise on regional surgery refers to Hoefftcke's splint in high terms.

The book is well written and shows what the extension principle of fractures and diseased joints is and the results its skilful application can achieve and as an exposition of the ambutatory treatment of such conditions is excellent in every respect.

INDUSTRIAL EDUCATION

Education and Industry. By Henry C. Link, Ph.D. New York: Macmillan Co., 1923.

The author's point of view is practical and experimental rather than theoretical and constructive. He anticipates critics of his book, who will say that it is lacking in constructive theories, by stating in his preface that he believes that "an orderly and successful attempt to make things what they should be is impossible without an appreciation and command of things as they are." Since the changes in the social and economic structure of the times are largely the results of an unprecedented industrial development, the centre of interest in the field of education today is undoubtedly the subject of the relation between education and industry. It is impossible to have so radical a change in the elements of a civilization without having a reflection of that change in the elements of its educational system, and without a considerable transformation in its educational methods.

He concerns himself in his book solely with a consideration of the outstanding and most promising manifestations of this change, his opinions and observations being based upon his work for the past several years as educational director for two large industrial corporations. The conclusion reached by him is that the efforts made in the field of industrial education will continue to fall wide of the mark unless they are based upon adequate information about the characteristics of industrial life. Such information may be obtained through vocational surveys such as have been made in a few of the States. At present numerous difficulties lie in the path of making such surveys; fundamental to solving these difficulties is a better general understanding of the common needs of education and industry. The book indicates the methods by which industries and public educators may cooperate to best advantage. Such cooperation will gradually provide the background of knowledge upon which future plans for industrial education may be most substantially built.

Chapters of special interest are those on industrial motion pictures, propaganda as an economic force, and subnormal workers in industry.

PSYCHOLOGY IN THE NOVEL

The Fruit of the Tree. By Hamilton Fyfe. New York: Thomas Seltzer, 1922.

In this novel some interesting psychological determinants are brought into play, and the story unwinds its usual unusual theme ending in the cowardly impasse of countless marital situations.

Muriel, the heroine, is the oldest of infinite children. Her mother dies of the last child, having sacrificed her life and all her hopes of personality for the bearing of children. The father suicides, unable to exist without the eternal mother. He disappears off a boat; plunging again into his prenatal medium.

On nothing a year Muriel goes to London to study law. She is going to make up to her mother for the dreams that were blighted by children. She does not want children. She drifts along, women friends, work here and there, finally some clerical work for a man who falls in love with her. After long debate they marry. Muriel in a flurry of casualness indicates that she is not interested in childbearing, but the lover does not understand and is bitterly disillusioned after marriage. Mentally they are good partners. Physically Muriel apparently does not exist. After her marriage she stops her studies, keeps her husband's house and helps him with his work, and amuses herself. All through the book she seems a singularly half baked individual, scintillating with charm when charm is required but in every other respect mentally and spiritually anesthetic. Needless to say her husband seeks and finds another outlet, a matronly animal who having got the children she longed for is content with them.

Then comes the dreaded, inevitable moment of discovery. The husband is in a bad way all round. Socially Muriel satisfies him; domestically for a time. Margaret, the mother of his children, satisfies him. A divorce means ruin for him socially, and more important to Muriel, the loss of a comfortable home and an income. Margaret doesn't care to give up the management of her children to their father. She can do without him perfectly well. Muriel does not want to give up the management of her home and her husband's incidental business affairs, especially the more important legal duties which will be coming his way. She also can do without him personally perfectly well.

And so the story ends, in an immoral, unproductive tangle. Clearly Muriel needs to have radical measures used on her to educate her out of the prostitute complex into which she has fallen. And her husband also needs to overcome the mother dependency that pictures to Muriel's unconscious the psychic configuration of her own father.

As the story now stands it gets nowhere. It is a tissue of contradictions, muddled thinking, yet arrives at a very frequent state of affairs in every day life. But the author accepts and leaves things. He sheers away from the task of making something of these commonplace mortals that might leave them a little less earthy than he found them.

◆

Medicoliterary Notes.

The Provincial Board of Health of Ontario has hit upon a unique way of helping to disseminate information about personal and public health. This is through the publication of a *Health Almanac.* The foreword states that this almanac is "dedicated to those who enjoy being well. Various phases of the work of safeguarding the health of the community and of the nation have been touched upon, so that those who read may realize that the subject is as complex as life itself." The pamphlet includes a monthly calendar giving the most important scientific or historical event of each day, with health maxims for days not especially significant historically. Popular paragraphs and articles on health matters are interposed between the calendars.

* * *

Rhus Dermatitis (Poison Ivy); Its Pathology and Chemotherapy, by James B. McNair, has been announced as one of the forthcoming publications of the University of Chicago Press. The discussion of the subject is very full and includes investigations from the pharmacological, botanical, chemical, and therapeutic viewpoints.

* * *

Current History for July contains an article by Clyde Langston Eddy entitled One Million Drug Addicts in the United States.

* * *

The summer play schools, which opened July 9th and which will be in operation until the end of August, have been an unqualified success. They include health instruction for the children in attendance, a canteen under the direction of a dietitian, and occasional trips to the country and to museums.

* * *

L'Anima della Donna is the Italian title of the book recently published in this country by Dutton under the title *The Soul of Woman.* The author is Gina Lombroso, who is a daughter of Césare Lombroso, the well known criminologist. The keynote of the woman problem, according to the author, is woman's realization that the distinction between sexes has been and always will be an insuperable obstacle to equality of the sexes in the day's work, and that she might as well make up her mind to accept things as they are and settle down to the home and children. Strange to say, Gina Lombroso, who is the wife of the famous historian, Ferrero, seems, in spite of her antifeminist attitude, to feel it perfectly fitting that she be known as a writer by her maiden name only, to qualify for the degrees of Doctor of Laws and of Medicine, and to take an active part in many economic and sociological movements and reforms.

* * *

Prof. Stuart P. Sherman, of the University of Illinois, has an interesting and entertaining article in the July *Atlantic Monthly,* on literary censorship. To "make the world safe for children and adolescents," he says, is a beautiful and inspiring thought, but it can't be done. Both the would be censors and some authors are in part in the wrong, but the solution of the problem is certainly over the heads of the police.

* * *

The National Committee for Mental Hygiene is making a study of the facilities in the public schools of this country for the training of mentally handicapped children. A questionnaire has been sent to supervisors of special classes and to superintendents of schools generally, to ascertain where special classes are in operation, how many children are examined and selected for these classes, the training they receive, the qualifications of their teachers, the supervision out of school hours, and what this training is accomplishing in the community. The replies received are now being analyzed, and the results of the study will be published for distribution.—*Mental Hygiene Bulletin.*

* * *

Since the war the British Isles have been using for food large quantities of eggs imported from China. Condensed egg powder was made from the yolks and the dried egg albumen preserved with acids. The Ministry of Health has decided that the cooked foods in which these substances were used are harmful and their sale for consumption has been forbidden under the food and drugs act.

* * *

The legislature of North Carolina has authorized the removal of the criminal insane from the state prison to the state hospital. A new building is to be constructed for the latter institution at Raleigh for the care and treatment of these cases.

* * *

Two interesting articles in the July *Atlantic Monthly* are The Physiologist in Industry, by Frederick S. Lee, and Progressivism, Old and New, by Charles Merz.

* * *

Announcement has been made that Dr. Charles K. Clarke, of Toronto, has had the honor of being chosen to deliver the Maudsley lecture for 1923 before the Medico-Psychological Association of Great Britain and Ireland. This lectureship was established upon a fund left by will by Dr. Henry Maudsley to the association. Only three lectures have thus far been given since Doctor Maudsley's death. The lectures were Sir J. Crichton Browne, Sir F. W. Mott and Sir Maurice Craig.

Practical Therapeutics

ORAL SEPSIS IN CHILDREN

By Henry S. Dunning, M. D., D. D. S.,
New York.

Volumes have been written during the past few years on oral sepsis and its relation to health and disease. The medical and dental professions are acutely alive to the importance of this subject. It is not for me, at this late date, to try to convince anybody that all chronic septic conditions are a serious menace. Hunter, Billings, Black, Hartzell, Colyer and a host of others have called attention to the rôle that oral infection plays in the human scheme of things. These writers have proved beyond much doubt that the mouth is a part of the human organism and that there is a close relationship between buccal infections and systemic disease. My only purpose in presenting this time worn subject is to plead for the children; to endeavor to arouse the medical profession to a greater interest in helping children grow unhandicapped into healthy and useful citizens. Are we doing all we can to lift the burden of sepsis from their young shoulders? Are we helping to carry their load, until they can carry it themselves? What are our hospitals doing?

The mouth is the most unclean cavity, bacteriologically, with which we have to deal. It harbors over one hundred different varieties of bacteria and is subjected to greater trauma than any other region. Thermal changes, in the form of food, hard and soft; medical agents; mechanical abrasion; poor dentistry, give the ever present bacteria plenty to do. On account of the conditions mentioned above, the buccal tissues, including the maxillary bones and mandible, often become infected. There are, generally speaking, three methods in which infections may enter the deep tissues of the jaws: First, the pericemental route, beneath the gingival flap; second, the intradental, within the tooth, through the dental nerve, or pulp canal; third, the hematogenous. The first two avenues are increased by the number of teeth present. In other words, the more teeth an individual has the more susceptible he is to oral sepsis for he has a greater line of defense to keep in repair. He has a larger area of gingival membrane to keep healthy and he has more dental nerves or pulps that must be *kept vital.*

It is more difficult for the child to keep up his first line of defense against the enemy, infection, than the adult. The resistance, as a rule, is not so good, and in the mouth the dental organs are in the developmental stage, with many irregularities that provide comfortable living quarters for bacteria. For this reason the average child finds it hard to keep his mouth clean. He is handicapped. The adult may appreciate the importance of oral hygiene; the child does not. The adult can often visit a dentist; the child can, too, at times, but does he receive the proper treatment that he requires? This last question I shall try to answer later. For the reasons given above, oral sepsis in the child is most common.

St. John Steadman (1) states that eighty per cent. of all children suffer from oral sepsis, that it is the most common of all chronic diseases. He also believes that chronic disease in the child, the effects of which spread over a period of years, must have a profound influence on its mental and physical growth, and he shows that many systemic disorders are traceable to oral sepsis. He calls attention to the fact that anemia, general mental and physical deterioration and loss of weight are due to unclean mouths. Colyer, in 1910, I believe, was the first to weigh children before and after the removal of infected teeth. He found that there was frequently a marked increase in the weight of a child after extraction and that this increase was too great to be ascribed to normal increase due to the growth of the patient. Rapid increase of weight does not always occur after the removal of the diseased teeth, as there may be other foci of infection that would have the same effect as infected teeth. He explains the loss of weight by the fact that children do not sleep well when dental irritation or pain is present. He has many charts and case histories to show rapid increase in weight upon the extraction of septic teeth. He also says that proper mastication is lost, as the child will not use tender, painful, infected teeth, and either refuses much of his food or swallows it before it has been properly masticated. The dental condition has often interfered with the sleep of the child for months unless the mother is observant, for the child does not always complain. Colyer further explains the loss of weight by the fact that infected teeth cause gastrointestinal disturbances, the main symptoms of which are gastric pain and diarrhea of an offensive character. He also cites fretfulness, night terrors and loss of appetite, which result in marked pallor of the face. He says: “If you take thirty children arranged in three groups, ten with all their teeth present and both teeth and mouth perfectly healthy; ten with most, or all, of their teeth removed but their mouths otherwise healthy, and the remaining ten with septic teeth and inflamed mucous membranes, it will be easy for the trained eye, aided, if you like, by the scales, to pick out the third group of children, but it will not be possible to separate the other two.” He goes on to say that the average physician is apt to treat the patient for gastrointestinal troubles first without paying much attention to the patient’s mouth. He cites the case of a child who was treated for gastritis for eleven months by a physician who disregarded the fact that the little patient had two badly abscessed molars. The gastritis cleared up shortly after their extraction.

Dr. H. Walker calls attention to the effect of dental disease in nursing women. He says that in many instances the infant loses weight when the mother has septic teeth. He goes into this question in detail and has about two hundred charts of cases showing that the infants generally gain weight upon the extraction of the mother’s septic teeth. Dr. Walker says also that it is important to see that there is no septic material in the child’s food and this can be done to a great extent by giving him a clean mouth.

Billings says, “The focus of infection which undoubtedly causes the streptococcus viridans bacteriemia and chronic malignant endocarditis is often from an alveolar abscess. Of this we have had numerous clinical examples. Coincident cultures from the alveolar abscess and the blood have yielded strains of the streptococcus viridans. When these nascent cultures were injected intravenously into animals, typical endocardial lesions have resulted. Billings says, further, that the deeper the infection is seated in the tissue and the greater the pressure of the accumulative bacterial products, the larger the amount of absorption. The tissue in which the infection occurs is also important. Mucous membranes absorb easily. An abscess enclosed by bone gives little chance for infiltration or extension; therefore, the pressure is great and the bacterial products are absorbed readily.

On account of the fact that most deep dental apical infections are locked in the spongy vascular bone where there is poor drainage, I feel that dental infections often do more harm than infections of the tonsils, as the latter drain more freely. If there is a sinus, the pressure is decreased and the amount of absorption is diminished. When abscesses or other lesions discharge their exudates into the mouth, they reach different parts of the alimentary canal where a new focus may be formed, especially if the pus supply is long continued, but secondary lesions may in turn also become foci for further and more general infection. Such conditions must not be mistaken for primary causes, but should be removed so as not to prolong and intensify focal disease.

We may also have other conditions, such as pharyngitis, otitis media and meningitis, formed through continuity of tissue. Some clinicians do not pay much attention to swollen submaxillary glands in children. Chronically swollen glands are a distinct detriment to the child. Such glands often remain large for a long time, become tender readily, and do not function as well as normal glands. Such glands are a handicap to the patient and these damaged organs are likely to break down at a later date if untreated. We should find out from whence the infection comes and remove its source, whether it be in the tonsils, the teeth or elsewhere; they often come from the teeth. Lymph drainage of the teeth and jaws is important.

Cleanliness will prevent oral sepsis, but cleanliness in the average child is a hard thing to obtain and to maintain. Many children have a bad start as regards their teeth. Many mothers wash their children's hands oftener in one day than they do their teeth in a week, and I believe that dirty hands are less dangerous than a dirty mouth. It is a tedious and irksome procedure to clean the teeth of children; to obtain the best results, one must make a sort of game of it and the parent must at times offer prizes for the cleanest teeth each week. The child must become familiar with the toothbrush almost as soon as the first teeth appear. The parents must see to it that the teeth are brushed carefully twice a day at least, and it is dangerous to leave it to the nursemaid, however trustworthy she may be. At an early age, say three to four years, the child should be introduced to another nurse who, we hope, is going to reduce the amount of oral sepsis by one half. The nurse I have reference to is the dental nurse, the majority of whom clean teeth much better than the average dentist and can handle these little tots more easily than can mere man. Children should be taken to the dental nurse or the oral hygienist twice a year and if this habit is started early they become so accustomed to the appearance of a dental office that it never holds any terrors for them. They think it's a great joke, if they are handled properly and are not hurt, and there is no reason for giving pain.

Many believe that pyorrhea can be prevented absolutely if the patient receives early and regular treatment at proper intervals all their lives, and that dental caries can be prevented to a very great extent. It should be our endeavor to prevent dental nerves or pulps ever becoming infected. We should not allow teeth to become nonvital, for as yet a vital tooth does not enter into the pathology of the mouth. We can prevent all these conditions in the children of the rich. It is being done every day. But what is being done for the poor? What kind of dentistry does a poor child in a large family get? He gets no preventive treatment, and is lucky if he gets to a clinic in time for extractions before he is in pain, and he is also fortunate if, when he gets there he receives the proper treatment in a way that does not strike terror to his poor little soul and make the operator forever his enemy. We need clinics and more clinics for children. We have no Forsythe and our George Eastman clinics in New York. What are our hospitals doing for the child's oral conditions? Almost nothing. There should be large clinics in this city where poor children could receive prophylatic treatment and I believe that every modern hospital should have an adequate dental staff to care for the mouths of children in order to prevent the distressing conditions which now exist. The public schools and the Red Cross are doing something to help the children, but as yet I am afraid that we have hardly scratched the surface of the problem.

It will take many years, I fear, to provide for the proper preventive treatment for poor children in this country and, for that matter, in any country. I am afraid that few of us will live to see this accomplished. Our chief problem is what to do *now* to help the child. The treatment of these conditions is surgical. It takes considerable courage to condemn many teeth in a child and I believe that most dentists lack this courage to a great extent. There is poor cooperation in this direction between the dentist and the physician. The physician sometimes orders teeth to be extracted and cannot get the dentist to perform the operation. He wants to wait until the "swelling goes down." It happens also that the physician tells the dentist to wait until the child "gets better." Neither are anxious at times to take the responsibility, and between the two there is nothing done until the infection has gained considerable headway and a good deal of damage has been done. A virulent tooth infection can cause a good deal of destruction in a short time. I believe all deciduous or permanent teeth whose nerves or pulps are exposed should be extracted *on sight,* the wound curetted if necessary, and the infected alveolar process treated and watched as any other surgical wound would be cared for. Dr. William L. Shearer says that not enough thought has been given to the surgical principles involved in certain pathological problems of the mouth. Surgical technic has been sadly neglected. Much has been done without sufficient knowledge of the pathological condition present. He also says that, where extractions have been numerous and the curettments extensive, the postoperative systemic conditions are at times alarming, and the tooth sockets drained for days and weeks with foul discharge, which oozed from the reddened inflamed gums, and responded slowly to any form of treatment. In addition to the local disturbance, systemic reactions frequently occur which are manifested by chills, fever and lassitude which would last for days. Increase in leucocyte count is common. I might say here that few men today believe in the extraction of many teeth at one time, the systemic postoperative reaction is often severe, but is not as severe in children as in adults.

Great good will result from our cooperative work when we understand better the pathology of the mouth and more surgical principles are employed. We have been content often with the mere extraction of diseased teeth; in many cases this is not enough. Radiographs taken later often show failure in our efforts to remove disease. Osteitis and granuloma often exist years after careless extractions and these often tend toward cyst formation.

The pediatrist should be able to check up mouth conditions and should be helped by the dental surgeon in their eradication. He should be able to recognize an inflamed gingiva and to express pus thereof as well as he is able to examine an ear. He should be able to test for vitality in a tooth and to read a dental film. We need extracting clinics in hospitals where fifty children a day can be cleaned up if necessary, surgically. We need intelligent young dental surgeons attached to the children's services in our hospitals, who will make rounds in the wards with the physician and who is not afraid to extract teeth. Prompt attention is necessary. I heard recently of an instance where in one of our best hospitals a call was sent for the dentist, who was attached to the hospital, to see a little patient with chorea. This patient was not seen by the dentist until seven weeks after he was notified. They say, "Save all the first teeth or else the jaw will be deformed and the permanent teeth will not erupt properly." I believe this theory has been proved wrong to a great extent.

Children as a rule take gas poorly and few approve of this anesthetic for very young children. I believe the open mask with ethyl chloride spray or ether with the tin mask is the best. Less nausea and vomiting will result if the anesthetist is particular about the amount of anesthetic used and frequently the patient can be sent home in an hour or two. Deciduous teeth sometime infect the permanent and great care must be taken to get good drainage for the erupting second teeth and to drain the surrounding bone and soft tissues. Care should be taken in extracting the first teeth not to injure the second teeth just below or just above, as the case may be. In closing, I wish to make a plea for a great dental infirmary for children in this city on the lines of the Eastman and the Forsythe clinics, where all kinds of preventive treatment can be given for these mouth conditions, where thousands of infected teeth can be extracted, quickly, cleanly, painlessly, and, in fact, surgically.

Letters to the Editor.

ETIOLOGY OF ULCER

To the Editor: New York, *June 7, 1923.*

It was with much interest I read the clinical observations on Peptic Ulcer by E. Palier, New York Medical Journal, June 6, 1923. Of especial interest was Palier's argument on the etiology of ulcer, based on his bedside and office observations. I would like to have obtained his protocols for his belief that microorganisms do not play a rôle in the etiology of ulcer.

Since my first observations on ulcer when in Virchow's laboratory in 1892 during the cholera epidemic to the present time, I have been impressed with the fact that infection plays no direct rôle in peptic ulcer and have so stated in my numerous publications on the subject. Ulcer conditions arising in infections, are not due to microorganisms but to tissue autolysis which I have shown occurs the same in the absence of infection. My experiments and deductions in nearly a hundred publications verify this. I regret that Palier did not read my protocols correctly, and the deductions made therefrom. In some of my experiments it was stated that beef extract was added to the regular rations of animals and in others, tannic acid and other agents. These agents interfered with normal digestion, absorption and assimilation. This induced general autolysis to provide for the induced caloric deficit. Then acute and chronic peptic ulcers were thus induced. In other animals, culture of Bacillus coli were added with the beef extract, but it was clearly stated the cultures did not cause infection but a condition in the alimentary tract that made autolysis necessary to supply the caloric deficit.

As I stated (*Journal A. M. A.*, June 9, 1906), "It is no less evident to one investigating the problem of the production and persistence of gastric ulcer, that we have here not a question of local pathology, but of general blood pathology of complement and amboceptor of cystolysis and autolysis," and summarized as follows: "Cystolysis and autocystolysis of the cells of mucous membrane of the stomach and the kidney and of the liver, were marked on microscopic examination. But there was no bacteremia, no inflammatory reaction in the form of wound cell infiltration such as one would expect in a reactionary inflammation induced by pyogenic microorganisms or their toxin. It was not a reaction to an infection, not a picture of a local active agent, but rather of a systemic condition of an induced cellular change."

By injecting homologous tissue extract into animals, I also induced ulcers. By inducing partial starvation in pregnant animals, erosions and ulcers also were found in the offspring.

I am glad that Palier has taken the position he does, based on his clinical work, but ultimate etiology can be best reached by animal experimentation. I wish also to correct his wrong interpretation of my many years of research. In scientific research, exact measurements and determinations can be made in every stage of the process. I have made these points on which my principle is based, fairly clear, in a recent presentation before the Academy of Medicine.

Fenton B. Turck.

Abstracts from Current Literature

DENTISTRY

Bacterial Origin of Dental Caries.—James McIntosh, W. Warwick James, and P. Lazarus-Barlow (*Lancet,* June 17, 1922), by a series of experiments, proved that the examination of selected carious material constantly contained a definite type of bacilli, which have the property of producing a high degree of acidity as a result of the fermentation of carbohydrates. It was shown experimentally that teeth left over prolonged periods in contact with cultures of the bacilli showed changes almost identical with natural caries, as was seen from the erosion of the enamel, the penetration of the dental tubules and the formation of foci of liquefaction. These bacilli resemble the acidophilus group of Moro in their resistance to and formation of acid, but biologically they differ in certain respects. The name Bacillus acidophilus odontolyticus, types I. and II., were proposed by the authors. The successful experimental production of artificial caries by pure cultures of these isolated organisms helps to establish the microbic theory of dental caries.

Oral Sepsis and Complications Due to Dental Disorders.—Artur Hauer (*Wiener klinische Wochenschrift,* April 20, 1922) cites the diseases traceable to dental disorders. Trigeminal neuralgia may be caused by pulp necrosis, thickening of the root, cement hypertrophy, pressure from foreign bodies and unerupted and dislocated teeth. There may be sensory, motor, secretory, or trophic disturbances, of which the sensory are the most common. Accommodation of the eyes has been markedly improved by the extraction of affected teeth; reflex asthenopia, miosis, mydriasis, ptosis, diplopia, nystagmus and strabismus have been improved or cured by extractions; neuralgia of the bulb, neuroparalytic keratitis, glaucoma, optic neuritis, photophobia, amblyopia and amaurosis have been traced to dental conditions. Disturbances of the tongue, palate, taste, ageustia, spasms of the chewing muscles, trismus, deafness and hyperacusis have disappeared after dental extractions. Reflex epilepsy has been caused by dental disorders. Hysterical toothache, oral hemorrhage and anesthesias, hysterical salivation and trismus, clonic spasms of the chewing muscles and pseudotraumatic hysterical ankylosis of the jaw have been noted. Trophic disturbances appear in tabes. Loss and loosening of gums, loss of teeth, pyorrhea, caries, dental tartar, fissured tongue, hypertrophy of the papillæ, ulcerations, chronic catarrhal stomatitis, odor of the breath from chloroform and rotten apples, delayed wound healing, and symmetrical neuralgias, point to diabetes. Hypochondria, mania, melancholia, hysteria and epilepsy have been cured by dental extractions and treatment. Dental nerves have degenerated after acute infections such as measles and scarlet fever. The upper intact incisors may become painful in coryza and after prolonged cold baths. Genital stimulation, uterine disorders, ovarian diseases and normal pregnancy have caused trigeminal neuralgia. The penetration of infectious material through the apical foramen produces granulomas. Hemorrhages from drugs or needle perforation may cause cysts in the presence of epithelial tissue, such cysts may fill the antrum. Lacrimal sac fistulas may be eliminated and tuberculous and actinomycotic dental fistulas heal after dental extraction; dental fistules at the angle of the eyelids, lid abscess and loss of an eye may follow. Fractured or unerupted teeth, sequestra, or foreign bodies may produce acute alveolar periostitis even in an edentulous mouth.

Oral Sepsis in Relation to General Diseases.—J. M. Ackland (*British Medical Journal,* June 3, 1922) asserts that, aside from the intestines, the alveolar process is the largest and most frequently diseased part of the body from which toxins are absorbed. Oral sepsis includes pyorrhea, alveolar abscess, and dead roots of teeth. The streptococcus causes the bleeding lesion, thus making way for the staphylococcus, which dissolves the tissue and creates the pocket. The commonest effect of oral sepsis is malaise, slackness, a tired feeling, lassitude and a general feeling of unfitness; also functional cardiac effects, as palpitation or nervous debility and depression. The cardiac conditions traceable to oral sepsis are ulcerative endocarditis, both acute and chronic, sometimes following the extraction of several septic teeth. Not too many septic teeth should be extracted at one sitting and the sockets should be well cleansed; strict oral asepsis is necessary. The use of hydrogen peroxide is recommended.

The commonest group of diseases following oral sepsis comprises neuritis, chronic rheumatism, arthritis and gout in those predisposed to it. The lesions may be plainly apparent or the streptococci, pus, and granulations may be seated near the apex of a tooth without local symptoms but with positive signs in the röntgenogram. In arthritic cases of dental origin, streptococci are found in the feces. Chronic inflammations of fibrous tissue and serous membranes are more often associated with dead teeth than with periodontitis; the streptococcus salivarius of acute suppuration is the one usually found in these cases. There may be no visible suppuration, but this does not necessarily mean that there is no infection present; the röntgenogram is of great assistance in these cases. The use of autogenous vaccines and the removal of affected teeth constitute the treatment. In active phthisis, the radical treatment of the oral sepsis should be delayed until a quiescent stage is reached and then carried out only very gradually. The same applies to chronic lymphadenitis.

Oral sepsis (pyorrhea) is the cause of nonhemolytic anemia in ninety per cent. of cases; sepsis of the antrum and nasal sinuses may be easily overlooked. Gastrointestinal disorders are often due to oral sepsis, associated with defective and painful teeth with consequent imperfect mastication. Traumatic lesions are sometimes aggravated and protracted as a result of oral sepsis. Oral asepsis reduces the frequency of chronic inflammations of the parotid and submaxillary glands and their ducts. Patients treated for Vincent's angina should not be discharged as cured until the fusiform bacillus is no longer found around the teeth. Oral sepsis may also produce chronic nasopharyngitis, septic bronchitis, skin disorders, or middle ear disease. Gastrointestinal disorders may develop in children. Night sweats are often present, tuberculosis is suspected, slight albuminuria may be found and nephritis may supervene. Tuberculous adenitis may be due to tooth infections. A child may not gain weight because of oral sepsis in the nursing mother.

Some Cutaneous Effects of Dental Sepsis.—Henry C. Semon (*Lancet,* May 6, 1922) points out that in some cases of chronic furunculosis the removal of a septic focus will lead to a cure, probably from, 1, the removal of an associated microorganism, such as the streptococcus, in a distant focus acting as an adjuvant to the staphylococcus infection, and 2, the reduction of the excessive blood sugar by an improvement in the patient's digestive power and a general metabolic activity following the removal of infected teeth. Furunculosis, urticaria, pruritus, and erythema multiforme may be associated with dental sepsis and disappear when these sources of infection are extirpated. The author found the streptococcus viridans and hemolyticus mainly responsible for his cases. All kinds of streptococci are normally found in the mouth. The reason why apical ends of devitalized teeth are apparently symptomless, but nevertheless are sources of metastatic infection, is that the bacteria are not usually encapsulated, but there is drainage into the circulation; swelling and tension therefore does not occur and hence there are no local symptoms. The portal of entry can be detected by the expert reading of röntgenograms and prints. It must not, however, be assumed that all cases of urticaria, erythema multiforme, intractable furunculosis and pruritus are due to dental infection.

Relation of Nutrition to Tooth Development and Tooth Preservation.—E. V. McCollum, Nina Simmonds, Ethel M. Kinney, and Clarence J. Grieves (*Bulletin of the Johns Hopkins Hospital,* June, 1922) describe a study of gross maxillary and dental defects in 220 rats which were typical of groups of experimental animals restricted to fifty-seven diets variously modified. From the results of this work the authors report that the internal structure of the skeleton of the rat can be changed at will by varying the animal's ration. Rickets, often of an exaggerated type, was produced by some of the faulty diets; others caused osteoporosis, and still others osteosclerosis. An analysis of the effects of the diets used on the skeleton indicates that the growth of the skeleton depends upon at least three factors: an organic substance present in certain fats which is not identical with the antizerophthalmic fat soluble A, calcium, and phosphorus. The percentage of oral defects was greatest in those rats fed the diets deficient in protein, calcium and fat soluble A. The rats on diets low in calcium showed the next highest incidence, and those on diets low in both calcium and fat soluble A had the third percentage of damage. The authors cannot at present name any one deficiency which specifically causes dental or oral disease, but they state it would appear that any slight variation in the American diet, which always so dangerously approaches the level of dietary deficiency, might become active at any period of lowered resistance or of physical or nervous stress.

GASTROENTEROLOGY.

Relation of Disease of the Gallbladder to the Secretory Function of the Stomach and Pancreas.—H. Ernest Griffiths (*Lancet,* February 10, 1923) shows that the gallbladder is only a unit in a definite digestive complex embracing the liver, gallbladder, pancreas and stomach, and that any disease affecting one unit is bound to be reflected in the whole system. Inflection of the gallbladder acting reflexly through the vagus nerve tends to cause hyperchlorhydria and regurgitation. If the sensory stimulus is greater, pylorospasm is the result of a sympathetic reflex through the ninth thoracic segment. Regurgitation from the duodenum may also be attributed to the unregulated flow of bile in cases where a gallbladder is no longer capable of acting as a reservoir. The pancreas is peculiarly prone to infection from the gallbladder. In the majority of cases infection occurs through the lymphatics, in others by the regurgitation of bile along the main duct consequent upon obstruction at the ampulla of Vater. This obstruction is frequently due to the spasm of Oddi's sphincter and occurs with pylorospasm. The secretion of the pancreas into the duodenum is seldom markedly diminished, the exception being in cases of catarrhal pancreatitis, but through lack of adequate admixture of bile the digestive function of the pancreatic juice may be seriously diminished. The internal secretion of the pancreas, except in rare cases, as in pancreatic necrosis, is not very much upset, although the increased amount of diastase in the urine and occasional positive Loewe's reaction are indications of some slight alteration. In some obscure cases of gallbladder disease, where the cause cannot be found by the ordinary clinical methods, exhaustive examination of the functions of the stomach and the pancreas may lead to a correct diagnosis.

Problems of Gastric and Duodenal Ulcer.—Berkeley Moynihan (*British Medical Journal,* February 10, 1923) considers a chronic ulcer (gastric or duodenal) as one with a visible and palpable lesion which has existed for months or years, with a crater of varying size, involving at least the muscular coat in depth and possibly extending through all the coats, in which case the base of the ulcer is formed by adhesions. Such ulcers are characterized chiefly by freedom between attacks of pain; the attacks are produced by the formation of new ulcers. Acute infections elsewhere may rouse activity in a dormant ulcer. An acute ulcer is one in which chaps, fissures, erosions, or extensive surface destructions of the mucosa, or even of deeper layers are found. Evidences of an impediment of the vascular supply may be found. Acute ulcers are multiple. The severe, protracted, and recurring attacks are produced by chronic ulcers. The following remarks are concerned only with chronic ulcer:

In a series of 718 cases reviewed, 531 were duodenal ulcer. Twenty-three cases showed gastric and duodenal ulcers combined. The mortality from gastrectomy in both types of ulcers was 1.6 per cent. The term juxtapyloric should be abandoned as it is unnecessary: the pyloric veins and pyloric white line clearly indicate the separation between the stomach and the duodenum. The chief clinical symptoms of ulcer of the stomach are pain, vomiting and hematemesis, the really important one being pain, which is characterized by its punctuality. The rhythm of the pain is noteworthy: that of gastric ulcer is "food, comfort, pain, comfort;" that of duodenal ulcer is "food, comfort, pain." The pain appears in an hour and a half in most cases of gastric ulcer and after two hours in most cases of duodenal ulcers. Seasonal variations are more common in duodenal ulcer. Hematemesis probably indicates gastric ulcer. In duodenal ulcer both hematemesis and melena may occur. Duodenal ulcer is far more common than gastric ulcer. The röntgenological evidence of gastric ulcer has the greatest value; the muscular tonicity of the stomach should also be investigated. Deformities of the duodenal bulb speak in favor of duodenal ulcer. The Rehfuss fractional gastric analysis is also valuable aid.

Medical treatment of the ulcer relieves the pain and curtails the attacks, but the period of repose is followed by a renewed and fiercer attack. However, healing of the ulcer may occur. In cases treated medically, the question of malignant degeneration must be given consideration. The author considers gastrectomy as thoroughly satisfactory in the great majority of cases; he prefers the anterior no loop method. He avoids gastrectomy only when the patient's condition is too poor to allow a major operation or when the location of the ulcer or any other of its attributes renders this operation impracticable or disproportionate to the patient's needs. He believes that by most watchful care, by direct transfusion of blood once or oftener and by the copious administration of glucose, with or without sodium carbonate, any required operation may be carried out safely.

Primary Union After Operation for Suppurative Appendicitis.—Robert G. Riddell (*British Medical Journal,* February 24, 1923) endeavors to obtain primary union, first, by protecting the wound as well as possible against infection, and secondly, if that fails, as it usually does to some extent, by trying to destroy the contaminating organisms. Where purulent fluid wells up immediately on opening the wound, there is little chance of keeping the wound clean, but in cases of localized abscess it is possible to protect the edges with tetra cloths stitched to the peritoneum, or with rubberbacked cloths held in place by special clips. If the abscess is small, the pus may be mopped out without soiling the wound, but even this may be difficult or impossible. It is advisable in all cases, therefore, to disinfect the wound after the peritoneum has been sutured. The appendix is removed with the usual technic, pus and fluid are mopped up as well as possible with dry gauze and the peritoneum and abdominal wall are firmly sutured. Various antiseptics were tried, but the author obtained the best results with flavine solution, 1:1000 in seven cases, all of which healed by primary union except one, where the tissues were soaked with purulent fluid as soon as the peritoneum was opened and where operation was long and the patient weak. The flavine should be very thoroughly swabbed into every corner of the wound, which should then be flooded with it and afterward gently dried out. Saline irrigations should be omitted, either for absorption or washing purposes.

Pyloric Stenosis of Infants.—Leonard G. Parsons and Seymour G. Barling (*Lancet,* January 13, 1923), in an analysis of ninety-four cases of this disease, of which thirty-six were treated medically, eight by gastroenterostomy after failure of medical measures and fifty by Rammstedt's operation, summarize their results as follows: 1. The results of medical treatment alone are very unsatisfactory. 2. Relief of the obstruction by Rammstedt's operation preceded and followed by a careful medical regime offers the best means of reducing the high mortality of this disease. 3. Rammstedt's operation allows the redundant mucous membrane to bulge and for a time abolishes the sphincteric activity of the pylorus. 4. Given early diagnosis and resort to treatment as above, they believe that the mortality can be reduced to twenty per cent. 5. Functional test meal examination of the stomach shows high rennin, high free acidity and high total acidity in the resting juice, delayed emptying and absence of duodenal regurgitation. 6. Chemical analysis of the stools negatives the suggestion that these patients are suffering from pancreatic insufficiency. 7. This and other evidence is opposed to the hyperadrenalism theory of the cause of hypertrophy as advanced by some authors.

Nondiarrheic Type of Celiac Disease: A Form of Chronic Fat Indigestion in Children.—Reginald Miller and Herbert Perkins (*Lancet,* January 13, 1923) describe a group of children who fail to thrive owing to their inability to absorb fat properly, and discuss the principles of their treatment. In spite of the absence of socalled diarrhea and of the typical pale, unformed and stinking celiac stool, this nevertheless is celiac disease in a mild form. These cases may be called nondiarrheic or dry form of celiac disease. A stool may contain a large excess of fat and yet be formed and colored if the contained fat occurs chiefly in the form of soaps; whereas, when chiefly in the form of fatty acids, the excess of fat causes the stool to be pale, unformed and offensive. The soapy stool is found in the nondiarrheic group and the fatty acid stool in the classical diarrheic form of celiac disease. Examples are quoted to show that the recognition of the nondiarrheic group suggests that the diarrheic cases may show to the naked eye considerable improvement in the stools without there being a return to the normal power of fat absorption. Its recognition also affords strong evidence against the view that celiac disease is due to an enteritis or that it has any essential connection with intestinal disease. A consideration of the two sorts of stool in celiac disease leads to the view that the pallor of the classical celiac stool is due to a masking of the pigment by the excess of fat present as fatty acid crystals.

Hypertrophic Pyloric Stenosis.—Leonard Findlay (*British Journal of Children's Diseases,* January-March, 1923) concludes that spasm of the hypertrophied pylorus is the most important factor in causing the symptoms. The results of treatment are invariably better in private than in hospital practice. Medical measures give as good, if not better, results than operation. Operation should probably be reserved for the youngest cases and for those seen soon after the onset of symptoms. The great danger to be avoided in any form of treatment is underfeeding.

CLINICAL MEDICINE.

Blood Destruction During Exercise.—G. O. Broun (*Journal of Experimental Medicine*, January and February, 1923) noted a great decrease in total circulating hemoglobin and red cell volume in dogs maintained under sedentary conditions when they are exercised vigorously during several consecutive days. This would appear to be the consequence of increased blood destruction, unrepaired for the time being. He found a definite increase in the percentage of reticulocytes after exercise in animals previously kept to a sedentary life. This fact, coupled with his previous reports of changes in the hemoglobin percentage, plasma—cell ratio, and red count, offers additional evidence of the occurrence of an increase in blood destruction under the conditions of the experiment. Replacement by transfusion of blood destroyed during exercise prevented the reticulated cell reaction. Animals which had been rendered plethoric and then exercised showed no increase in reticulated cells, while plethora lasted.

In the fourth paper of the series (*Journal of Experimental Medicine*, March, 1923), Broun deals with the development of equilibrium between blood destruction and regeneration after a period of training. Animals which have been confined for but a short time do not show as large a decrease in cell volume following exercise as those which have been confined for several months. A dog which has been kept for a long time under sedentary conditions and then exercised continuously for several weeks will show a decrease in cell volume in the first or second week of exercise, but this is usually made up by the end of the third week. Apparently by this time the hematopoietic tissues have adapted themselves to the increased demands made upon them by the hastened rate of destruction. Autopsies on the experimental animals showed that the weight of the spleen is considerably greater in the exercised animals than in the controls, or than is usual with normal dogs.

Significance of Colloid Lability in the Blood.—J. von Darányi (*Wiener klinische Wochenschrift*, November 9, 1922) asserts that the determination of the colloid lability, as a rule, gives evidence of the extent of tissue destruction. It is of practical use in many respects. Inasmuch as the reaction in active tuberculosis and syphilis runs parallel with the extent and activity of the process, it may well serve as a quantitative measure in the more qualitative reactions of immunity. The reactions for syphilis, for example, may be three plus positive in entirely latent cases and negative in the most severe malignant forms; the tuberculin test is sometimes inversely proportional to the severity of the disease; the colloid lability, however, gives more accurate information as to the activity and extent of the disease. It gives more information as to the activity than the temperature, radiography and many other symptoms. This reaction may well be used as an objective therapeutic control according to the different conceptions (in syphilitic, tuberculous, and carcinomatous therapy). In pregnancy (indication for interruption in active tuberculosis) only the reaction proposed by the author is applicable, because the other tests are strongly positive in pregnancy alone. The use of this reaction in differential diagnosis, however, is limited, but it is useful in deciding the question of the existence of benign or malignant necrosing tumors, and also whether superficial catarrhal or deep processes, or whether organic or functional diseases are present. The determination of the colloid lability leads rather to a diagnosis of activity as to toxin formation and tissue destruction than to a specific diagnosis.

Studies in Focal Infection.—R. N. DeNiord and B. J. Bixby (*Journal of Laboratory and Clinical Medicine*, July, 1922) found in a series of several hundred cases that certain changes invariably took place in the blood chemistry of patients having a focal infection. The main fact emphasized in this paper is that infections, whether producing pus or not, give rise to a nuclear degeneration of a proteolytic type from the nuclei of the cells so broken down, the end product of which is uric acid. High uric acid in the blood, therefore, is indicative of nuclear degeneration, which in turn may mean focal infection. There are, of course, factors other than chronic infection which will cause a high uric acid, such as leucemia, primary anemia, cachexias, massive doses of x ray and radium, etc., but all of these conditions are susceptible to diagnosis and elimination .

The authors point out that the presence of a high blood uric acid should be followed by a thorough search for all possible primary foci of infection, and the elimination of all foci of infection will be followed by a return of the uric acid to normal. In the authors' experience practice based upon this assumption has led to satisfactory results. A table giving the results of their studies includes such diagnoses as erythema nodosum, sciatica, arthritis, gout, chorea, myalgia, and neurasthenia. In the series the uric acid varied from 3.2 to 4.5 mg. in 100 c. c. The treatment consisted variously of tooth extraction, tonsillectomy, appendectomy, or cholecystectomy. After appropriate treatment the uric acid ranged from 1.2 to 3.7.

For many years rickets was looked upon as a disease of malnutrition in which there was a deficiency of mineral salts, particularly of phosphorus and calcium. Many theories have been advanced as to whether the deficiency of intake of these salts, the failure on the part of the infant to assimilate them, or their too rapid excretion from the body was the principal cause of the trouble. It is only comparatively recently that the theory of the disproportion between the amount of phosphorus and calcium in the system has been looked upon as playing a greater part than the deficiency in the amount of either or both present in each case. So much importance is now attached to this fact that two forms or kinds of rickets are recognized as occurring separately and distinctly from each other; one, in which the calcium is low and the phosphorus normal or above, being referred to as a low calcium rickets, and the other, in which the phosphorus is low and the calcium normal or above, as low phosphorus rickets.

Many authors, according to Tisdall, have been working on this matter, their views being based on the experimental production of rickets in rats, followed and supported by clinical observations in both private practice and institutional work. At a glance this may not seem to be a matter of great importance, and yet, if a physician should administer phosphorus to the limit in a case of low calcium rickets, in which the phosphorus was normal or above, you can readily see that, even though no harm was done by the excess of phosphorus in the system, there would be considerable danger of tetany developing, due to the prolonged period of calcium deficiency. On the other hand, suppose conditions were reversed, and calcium was being energetically administered in a case in which it was already normal, or above, while the infant's system was craving phosphorus, which might be fifty per cent. or more below normal in that patient at that time, one must admit that, to say the least, the rachitic condition would not be helped, even though the baby was not harmed.

I imagine I hear some of you say, "I always administer both calcium and phosphorus in all my cases of rickets," and I grant you that such is usually the case, and is perfectly proper, but I submit that to give the maximum of the one that is deficient and the minimum, if any, of the one that is normal or above, would surely produce better results in a shorter space of time, and tend to head off some of the complications and sequelæ that are frequently so disastrous to these patients, either in costing them their lives at the time, or in deforming or crippling them for life afterward. I also imagine I hear others commenting on the difficulty one would have in getting the calcium and phosphorus percentage estimated, which is quite true, a laboratory with an experienced person in charge being necessary for this purpose, but it seems to me that, nowadays, there are very few localities in which this could not be done, particularly where the information, when obtained, was going to be of so much value to the physician and so much benefit to the patient. On an average a little over ten mg. of calcium to the hundred c. c. of serum and a little over five mg. of phosphorus to the hundred c. c. of serum, has been found to be normal, and the diagnosis of rickets in all cases where either of these amounts has been considerably reduced has been supported and verified by the clinical symptoms present, whereas such has not been the case where there has been reduction in both of these substances; in other words, as mentioned above, it is rather the disproportion between the two, due to the reduction of only one, that seems to afford at least some explanation for the occurrence of the symptoms.

To illustrate what may be a bad result from delay in the proper treatment of the case, according to whether it is a low calcium rickets, or a low phosphorus rickets, I might mention the fact that it is in cases of low calcium rickets that tetany occurs, and, therefore, in such a case it is the calcium that one should be pushing the hardest, and giving but little, if any, phosphorus, as the amount of this ingredient present will be at least normal, if not above. To

head off the development of tetany the child should be what might be called calciumized as quickly as possible, which usually would not be the case were one simply administering a calcium and phosphorus combination on the principle that he was dealing with a case of rickets, without having made any attempt to ascertain what form of the disease was present. It is true, of course, that tetany occurs entirely independent of rickets, but it is at all times a low calcium condition, whether it be present as a symptom of, or entirely independent of, rickets, and in any event, therefore, it is the use of calcium that is indicated, and not phosphorus.

With this explanation of my reason, perhaps my apology, for discussing this subject, I might at this time call attention to some facts in the etiology of rickets with which one may be familiar, but which at times may escape attention when endeavoring to locate the causative factor in the given case.

Hess divides the causative factors into four classes: 1, dietetic; 2, hygienic; 3, infectious, and 4, endocrinous, but admits that the latter two probably play a small part if any, the dietetic and hygienic factors offering the best solutions for the pathogenesis of rickets. He also calls attention to climate, environment, season, age, heredity and prematurity as predisposing or exciting factors, or both, all of which have no doubt been noted at various times in different cases by all. As to season, both the bottle and the breast fed baby are affected, the condition being worse in the winter and spring months. In the case of the breast fed baby, the mother does not get as much physical exercise in the fresh air and exposure to sunlight during these months, and, in addition, her diet of necessity is restricted, so far as fresh vegetables are concerned. When it comes to the bottle fed baby, it has been proved that the vitamines in the cow's milk are much reduced during the time the cow is stall fed as compared with the months when it is pasture fed. As to age, from the sixth to the sixteenth months the largest number of cases seem to occur, although others have reported its much earlier development, even being present at birth, but this is questioned.

While heredity is probably only a predisposing factor in exceptional cases, prematurity undoubtedly plays an important part in many cases, as, according to Hess, "the mineral content of prematures is below normal, as two thirds of the minerals are deposited during the last few months of fetal life, the fetus at six months containing thirty grams and at nine months one hundred grams. In the newborn, fully seventy-five per cent. of the ash content consists of calcium and phosphate, consequently rickets being a disturbance in the calcium and phosphate metabolism, the more premature the infant, the greater the deficiency in calcium and phosphorus, so that the surplus supply is exhausted earlier than in the full term."

Underfeeding is another factor in the development of rickets in the premature. The low calcium content of human milk and the difficulty of metabolizing even this food in sufficient quantities to prevent drawing on the inherited supply may be an active factor. When we come to take up the question of diet as a causative factor in a given case, we may have quite a problem on our hands. I feel, as do many others, that prolonged breast nursing, such as is so common among the negro and Italian races, is a fruitful source of trouble, and serves largely to explain the existence of rickets in breast fed babies. Then, too, if the recent work of Smith and Merritt is to be given its full value, we have all evidently been having the wrong idea for a long time in reference to the correct rules governing breast nursing and bottle feeding. After an exhaustive study of the subject, these authors present the following summary of their most interesting paper:

"From the preceding it is evident that nursing infants obtain the greater part of their feeding of breast milk in the first few minutes, from forty to sixty per cent. in the first two minutes, and from sixty to eighty-five per cent. in the first four minutes. This holds true whether the supply is abundant, moderate or scanty. After eight minutes few babies get any milk whatever. Only seventeen of our observations show any increase in weight after eight minutes; fourteen of these were from Tables I and II—good feedings; only three babies obtained milk after ten minutes. A few larger, vigorous infants, nursing from an abundant supply, may get small amounts of milk up to sixteen minutes.

"The babies who need both breasts usually get less from the second than from the first side, except when one regularly yields a better supply. The rate at which a baby gets milk from the second breast is similar to that of the first breast, i. e., from forty to sixty per cent. in the first two minutes and from sixty-five to eighty-five per cent. in the first four minutes. After that very little is obtained. The time after which a baby gets no more milk is usually shorter on the second breast than on the first.

"The poor feedings have been completed in a shorter time than the good ones. When the breast supply is evidently failing, the baby gets all he can in from three to five minutes, as a rule. It does no good to leave a baby a longer time (from fifteen to twenty minutes) at a failing breast in the hope of eking out a meagre supply.

"If a baby empties the breast in from five to eight minutes and shows no signs of discomfort from an adequate feeding obtained in that time, there seems to be no good reason why he should not take his bottle in about the same time. If the nipple holes are of good size so that the milk flows freely nearly all strong infants will finish the bottle in less than ten minutes. They evince less distress than the nurse does over the rapid feeding. On the other hand, a slow nipple either discourages the baby so that he will give up in disgust before he has finished the bottle, or else makes him swallow so much air that he vomits or has colic. We believe that from eight to ten minutes should be ample time for any but the feeblest infants to take a bottle.

"The method of fractional weighing may well be applied to every breast fed baby since it is the only way by which we can determine how long a given baby should nurse, and whether he needs one or both breasts.

"It seems fair to conclude that a normal baby who gets enough milk from one breast needs to nurse, as a rule, only from six to eight minutes, rarely from ten to twelve minutes.

"A baby who needs both breasts may nurse from six to eight minutes on the first and from five to seven on the second. Very few babies need as long as ten minutes on a breast. A good many will empty the breast in four or five minutes.

"There is no evident reason why a baby should not take a bottle feeding as fast as he does one from a breast."

In view of the foregoing, have we not probably been unconsciously and unintentionally insisting that the mother follow certain rules in the way she nurses her baby that were not only detrimental both to mother and child and to the milk supply itself, but also to the proper nutritional development of the child along the lines of providing it with antirachitic and antiscorbutic protection? This leads me to call attention to one important fact, namely, that when examinations of human milk are made to determine its quality, separate tests should be made of the milk from each breast, and preferably from the total twenty-four hour collection from each breast. The custom of pumping milk from each breast separately and then pouring the two together before the examination is made has many objections, as the difference between the two is oftentimes very great. I have in mind at present a woman from one of whose breasts the milk was nauseatingly sweet and the other equally nauseatingly salty. Then, too, the percentage of the various ingredients differs materially, and is evidenced by the frequency with which one or the other has been used, the mother often using one breast more frequently than the other because of the larger quantity of milk present therein and the greater satisfaction it gives the baby, when, as a matter of fact, if the one containing the smaller quantity were used the more often, the amount would probably be materially increased. Of course, as you are well aware, the only way to determine the quantity is to weigh the baby before and after nursing from each breast separately, at different times of the day over a period of a number of days.

When it comes to the bottle fed baby, we have an even greater problem on our hands. It has been estimated that cow's milk contains five times as much phosphorus as human milk, and four times as much calcium, and yet we have by far the greater percentage of cases of rickets in the bottle fed. What is the explanation? Many theories have been advanced, all no doubt of some value, but, personally, I believe the association of hygienic conditions in many cases, such as deficiency of sunlight and fresh air, neglect of such body functions as digestion and bowel action, deficiency of elimination, especially by the skin, due not so much to lack of bathing as to improper clothing, etc., need to be given more consideration in association with diet than has been our custom in the past, as we have been in the habit of looking upon these cases as being too exclusively due to diet.

Holt, in association with Courtney and Fales, in studying the question of calcium metabolism in relation to the great amount of this material present in cow's milk, stated that "in general he found that thirty-five to fifty-five per cent. of the calcium intake was absorbed. An excessive calcium intake did not increase the calcium absorption as the excess was excreted. If the intake of calcium oxide was very low, less than 0.10 gm. to the kilogram, the absorption of the calcium oxide was below the necessary requirements, and a negative calcium balance might develop. They found the best absorption of calcium obtained when the calcium intake bore a definite relation to fat intake," while McCollum believes that "in infants the reason that rickets develops is because the dilution of milk is such as to destroy or alter the proper mineral proportions when nothing else is added to the diet," and Voit asserts that "excretion of calcium is almost entirely through the intestines, especially the large bowel, only five to ten per cent. being excreted by the kidneys. Children suffering from chronic intestinal indigestion show a low calcium absorption."

When we take up the question of phosphorus metabolism, we find conditions in many respects are quite different, for example, Schabad states that "two thirds more of the phosphorus is normally excreted by the kidneys, the rest from the bowel, the proportion being eighty to twenty in the breast fed and sixty to forty in the artificially fed. During florid rickets the relations are sixty-five to thirty-five and forty to sixty respectively, and there is an absolute increased excretion of phosphorus. As the disease is arrested the proper proportions are reestablished and for a time there is a greater retention of phosphorus than normal," while Howland and Kramer have shown that "the blood phosphate is low in the blood plasma of rachitic children, and that the administration of codliver oil causes a marked rise." Hess and Gutman have demonstrated similar changes following exposure to the sun's rays and by use of quartz lamps. Hess claims that "phosphorus in the blood can be increased by feeding prosphorus by mouth."

I cannot but feel that McCollum's statement that "rickets develops because the dilution of milk is such as to destroy or alter the proper mineral proportion when nothing else is added to the diet," goes the farthest of any toward explaining the reason for so many cases in bottle fed babies, so far as the dietary cause for the trouble is concerned, but, as mentioned above, I do not think we should blame diet so much *per se,* but rather associate the probable causes more than we have done in the past. Hess, in summarizing his article on rickets, says, "It may be stated that rickets is a nutritional disturbance, especially affecting the osseous, muscular, and nervous systems, with resulting lesions due to improper utilization of calcium and phosphorus," which I believe explains the matter as fully and clearly as can be done from a diet standpoint.

It is quite unnecessary for me to describe the symptoms of rickets, although it may not be amiss to mention some of the early symptoms, as they are the ones most likely to be overlooked, particularly if one is not suspecting the case to be one of rickets. Among the earliest signs are fretfulness, irritability, restless sleep, excessive perspiration about the head, especially when eating and sleeping, pallor, constipation, frequently alternating with diarrhea, pot belly, umbilical hernia, and general backwardness in physical development, the infant not being able, as it should, to support its own head at four months, sit erect at seven months, stand at ten months, walk with help at twelve months and alone at fifteen months. There is usually a delay in the closure of the sutures and fontanelles, the anterior fontanelle not being closed by the eighteenth month, as it should, although the posterior may be closed, as it normally is, by the second month. Getting uncovered during the night is an important symptom, and I would remind you that the way in which this occurs needs to be noted; for example, if the child gets uncovered by crawling up on to the pillow, it is more likely to be a case of enlarged adenoids, the child suffering from air hunger, and seeking the highest place in order to breath easier, while if it gets uncovered by kicking off the bed clothes, it is quite suspicious of rickets. When it comes to the earliest changes in the skeleton, the socalled rachitic rosary, Harrison's groove, the squared head, flattened on top, and with marked frontal and parietal eminences, and the nodular enlargements in the long bones at the junction of the epiphyses and diaphyses are among the earliest and most noticeable signs, although the one that is considered pathognomonic of rickets is craniotabes. Dentition is frequently delayed, the teeth are often irregular and the first teeth are subject to early decay. A marked grade of secondary anemia is usually present, explaining the pallor frequently mentioned, and various nervous phenomena are invariably present.

Other changes in the skeleton that develop later are kyphosis, scoliosis and bowlegs. In reference to the kyphosis, which may sometimes be of tuberculous origin, I might mention that an important differential point between these two forms of the condition is that the kyphosis of rickets is reducible, by placing the child on the abdomen and overextending the thighs, which would not be true of tuberculous kyphosis. So far as the scoliosis is concerned, this usually occurs in the same direction, being largely due to the fact that most mothers carry their babies on their left arms, in order to have the right hand free, thus raising the left side of the pelvis, and allowing the right shoulder to droop, causing a bending, as it were, in the centre. Such being the case, much of this scoliosis could be avoided by educating mothers to carry their babies alternately on each arm.

When it comes to bowlegs, while too early walking, the body being too heavy for the legs to bear, and the diminution of mineral salts in the bones of the legs themselves, are both important factors, one that is frequently overlooked is the too long wearing of the diaper, the restriction in the action of the hip joints resulting therefrom, causing the child to assume an unnatural gait; in other words, mothers should be instructed to commence training their infants for the evacuation of the bladder and bowels at the third month, so that, by the time the child is ready to walk, its habits in these respects, at least so far as the bowels are concerned, will have been sufficiently developed along the line of cleanliness for diapers to be dispensed with.

In prognosis, rickets is essentially a chronic condition, although its duration may be materially influenced by the proper treatment, and particularly if that treatment be started early. However, in spite of this, some of the deformities may persist throughout life, as, for example, those of the pelvis, often observed by obstetricians. Rickets is never fatal *per se*, but it is a most important factor in reducing the child's resistance and impairing its vitality, thus increasing its susceptibility to various infections and diseases, especially those of the alimentary and respiratory systems.

As Hess states, "death may result from spasmophilic manifestations, more especially convulsions," and it is in this connection that I embody tetany in the title of my paper, because, as very well expressed by Shipley, Park, McCollum and Simmonds, "tetany is essentially an expression on the part of the nervous tissues of an insufficiency of the calcium and phosphate ions of the body fluids. Tetany is frequently associated with rickets because rickets is a disease in which the calcium ion in the body tissues and fluids is subject to variations. Tetany may occur independent of manifest rickets. Since tetany may occur with the low phosphorous form of rickets, it does not serve to mark off one form of rickets from the other. Tetany, however, is essentially associated with the low calcium form of rickets and, for all practical purposes, the low calcium form of rickets is the rickets of tetany. While occasionally cases are seen in which clinical evidence of rickets is not demonstrable, these cases are on the whole exceptional. On the contrary, many cases of rickets, even very severe types, exist in which tetany does not supervene."

As in rickets, diet, prematurity, age and season play a part in the etiology of tetany. So far as diet is concerned, however, while we see many cases of rickets in breast fed babies, we rarely see cases of tetany among the breast fed; in fact, breast feeding is one of the best methods of treating a case of tetany, and will produce the most prompt results in its cure, cow's milk and proprietary foods seeming to be the principal offenders. As stated under rickets, prematurity is a markedly predisposing factor, and for the same reasons as given under rickets, but breast feeding has a more beneficial effect in the prevention of tetany than it does in the prevention of rickets, largely, perhaps, because tetany, as mentioned above, is essentially associated with low calcium, while rickets may be due to either low calcium or low phosphorus. Concerning the effect of season, here again both the time of the year, and the etiological factors run parallel with rickets, which is equally true when it comes to age in its relation to tetany. Kramer and Howland found that "in children suffering from rickets alone, the phosphorus of the blood serum is low, and the calcium not far removed from the normal; in children suffering from manifest tetany complicating rickets, on the other hand, the calcium is low but the phosphorus not far removed from normal." Under these circumstances, one question is, what will reduce the calcium content, or the phosphorus content, in other words, affect only one or the other, and not both, and second, why is the calcium content of cow's milk so often reduced, causing tetany, while that of human milk is so rarely reduced that, as mentioned above, cases of tetany almost never occur in the breast fed. One theory advanced for this is the socalled parathyroid, MacCallum and his coworkers finding "that the parathyroid gland regulates calcium metabolism and that failure in its secretion results in a lessened retention." Granting that such is the case, why is not the parathyroid gland as often influenced in its regulation of calcium metabolism in infants fed on the breast, as in those fed on cow's milk? Can it be that it is this regulating influence of the mother's parathyroid gland, acting on her milk, rather than in the infant's parathyroid gland, acting on its digestive functions? Grove and Vines, in the *British Medical Journal,* report several cases, which, while covering a variety of conditions, were all due to some chronic toxic state, and all had a deficiency in the ionic calcium of the serum, due, perhaps, to a combination of calcium and toxin.

In the majority of cases it was possible to find a primary septic focus, and sometimes the administration of parathyroid caused a hidden focus to become apparent by increasing the leucocytic reaction to the attacking organism. An examination of the literature tends to establish the proposition that the parathyroid glands have a double function; first, a regulation of calcium metabolism, and, secondly, the power to render a certain toxic substance harmless.

Further, it may be noted that in animals whose parathyroid functions have been interfered with, either by removal or ligation of the glands, if tetany does not supervene shortly and so cause death, there is a strong tendency for the animals to die from an infective process.

It is possible that the continued absorption of toxic substances from some primary septic focus may eventually lead to partial parathyroid insufficiency and a disturbance of calcium metabolism. These two conditions will cause a decrease in the resistance of the tissues, so that they are rendered more liable to a secondary process. The locality of the latter lesion will depend on local conditions of nutrition, blood supply and so forth. As Brown, Courtney and MacLachlan state, it is evident "that there is some other factor than food which is responsible" for the disturbance of the phosphorus calcium ratio. One fact to be borne in mind is that while some of the work that has been done along these lines has been on whole blood, some has been done on blood serum, and Tisdall feels that perhaps the difference in the results of his investigations and those of Hess may be due to this.

To quote Hess again: "There is, however, grave question as to the relationship of parathyroid dysfunction and tetany in the infant. Pathological studies lead us to believe that parathyroid lesions in infantile tetany are the great exception. Parathyroid lesions have been described in patients who have shown no evidences during life of the pathognomonic findings of tetany. In summarizing the pathogenesis we may state that a diminution of the calcium salts in all probability is the most important factor in the development of this condition. However, the possibility of an absolute or relative excess of the phosphates, especially the sodium and potassium salts, playing an important rôle cannot be overlooked. Abnormal ratios in the body salts as in rickets play an important rôle. The relationship of disturbances in parathyroid functions to the diminution of calcium tissue content must be made the subject of further study before its importance can be fixed. Infections are the most frequent factor in precipitating manifest symptoms in the latent cases. The seasonal incidence emphasizes the importance of the relationship between active rickets, infections and spasmophilia."

Concerning the symptoms of tetany, they should be arranged in two classes, latent and active, the latent consisting of Erb's sign, being an increased electric hyperexcitability; Chvostek's facial sign, being a hyperexcitability of the facial nerve, and Trousseau's sign, which is elicited by moderately compressing the nerves and vessels of the arm, midway between the elbow and shoulder, producing the socalled obstetrical hand. Of these three signs the Chvostek is perhaps the most significant of tetany, at least in early infancy. When it comes to the active signs carpopedal spasms, convulsions and laryngismus stridulus are among the most common, and unfortunately, as tetany so frequently occurs at about the same age as dentition, this is frequently blamed for the convulsions.

As to the prognosis of tetany, this should always be guarded, although, on the whole, it may be said to be guardedly favorable, but so many things play a part in influencing the prognosis, such as the frequency and severity of convulsions, the presence of an enlarged thymus, such complicating diseases as pertussis, and the presence or absence of an associated rickets, etc., that the prognosis in each case of tetany is a law unto itself. As in rickets, while in most cases, if the child recovers, there are no bad aftereffects, yet, in some cases of tetany the children show for years after their recovery various nervous manifestations, and Hess even states that some "show mental retardation."

In considering the treatment of the two conditions, i. e., rickets and tetany, their close relationship to each other, from the viewpoint of etiology, naturally makes the treatments similar. For example, in both cases diet is the first and most important factor, and human milk by far the most valuable article of food for these little patients, provided, of course, that they are under the age of one year, for, as mentioned above, after this age human milk is one of the most common causes of rickets. Of course, the diet of the mothers in these cases is as important as that of the infants and needs to be as carefully investigated. Plenty of milk, eggs, butter, and green vegetables are essential, meat not being nearly as productive of calcium, phosphorus and vitamines as it is frequently given credit for. So important is the use of human milk for these little patients that, when the mother's milk is not available, wet nurses should be obtained when possible. In the absence of human milk, in cases of rickets, cow's milk will be the next best form of food, but, in cases of tetany, this is not by any means true, as we have shown above that it is in infants fed on cow's milk in which we get the greatest number of cases of this disease. For this reason, in cases of tetany, goat's milk, well cooked gruels, fruit juices, soups made from vegetables, cereals and meat, are preferable to cow's milk, and, if the case be one of tetany only, i. e., one without rickets, this diet would be an excellent prophylactic against the development of rickets.

It is not unusual in cases of rickets and tetany, whether occurring alone or in association, for symptoms of scorbutus to be present, and here again the diet mentioned would be indicated, both as a prophylactic, if scorbutus is not already present, and for its active treatment, if it is present. While on the subject of fruit juices, I might call your attention to the investigation of Gerstenberger, of Cleveland, in which he showed that orange juice had a marked effect in increasing urination, and, by depleting the system of considerable fluid in this way, tending rather to diminish than to increase bowel action, as we were taught in the past to believe. Gerstenberger also, as well as other investigators, has shown the great value of strained canned tomato juice as an antiscorbutic in these cases.

To refer again to cow's milk, the question of raw milk versus pasteurized milk should be considered. Undoubtedly, were raw milk as safe as pasteurized milk, it would be the one to use, as, while pasteurization does not alter the fat, carbohydrate or protein percentage, nor, perhaps, diminish the nutritive value of the milk, it surely does change the chemistry and deprive the milk of some of its socalled pep; in other words, it has been proved conclusively, I believe, that the vitamine content has been diminished by pasteurization. Another point to bear in mind in reference to pasteurized milk is that it does not keep very well nor very long after pasteurization, even where all precautions are taken, such as placing it in an icebox, etc., and, naturally, still less well would it keep in the homes of those in which we find most of our cases of rickets and tetany, in view of the unhygienic and unsanitary surroundings and the lack of appreciation on the part of the parents of the necessity for extreme cleanliness. I remember some years ago a physician from London addressed the Philadelphia County Medical Society on this subject, and showed that the numbers and kinds of bacteria present in pasteurized milk a day or two after the pasteurization process had been completed, even though the milk in the meantime had been kept in the most cleanly and sanitary way, were far in excess of what had been present previous to the pasteurization, the only question being as to the relative virulency of those before and after pasteurization.

When it comes to fruit juices, my custom is to start their use at the third month in bottle fed babies, and at the fifth month in breast fed babies, giving equal parts of fruit juice and hot water, usually an ounce of each, sweetened to taste, between feedings. Except for stewed prune juice, stewed rhubarb juice, and strained canned tomato juice, I use exclusively raw fruits, obtaining the juice from them by passing them through the ordinary little meat compress. Meat juices are also beneficial, particularly in view of the secondary anemia so commonly present, but one must bear in mind the necessity of moderately cooking the meat because of the danger of tapeworm if the meat be too raw.

Next to diet in the treatment of these cases come the effects of the sun's rays, and these infants should spend several hours a day outdoors in the sunshine, weather permitting. In the absence of opportunities for exposure to the sunlight, as, for example, in bad weather, the ultraviolet rays may be used with beneficial effect. The mercury vapor quartz lamp is frequently employed, and is as beneficial in the colored race as the white, as has been proved by several investigators. So far as the treatment of rickets and tetany goes, codliver oil heads the list of remedies, both for its prophylactic and its curative value. If phosphorus is added to the oil in doses of one two hundredth of a grain of phosphorus to one dram of codliver oil, the benefits are even more marked, in cases of low phosphorus rickets, while in cases of low calcium rickets, or tetany, either separately or in association, some form of calcium should be added to the codliver oil, and I am very fond of using the syrup of the lactophosphate of calcium in dram doses for this purpose. I realize the objection to the taste of codliver oil, but this may be overcome to a great extent by either administering it in fruit juice, or giving the oil ice cold from a warm spoon, the under surface of which has been covered with some pleasant tasting ingredient. I might mention in passing that the oil should always be kept in a stone jar or crock in the icebox, and not allowed to remain in the bottle in which it is purchased. Inunctions of two parts codliver oil and one part soap liniment following the daily bath are also of benefit, the soap liniment overcoming much of the unpleasant odor of the oil, facilitating its absorption, and preventing the skin from becoming dry and scaly.

SUMMARY.

1. There are two kinds of rickets, 1, low calcium, and 2, low phosphorus, in which one or the other of these substances is below normal, the other being normal or above.

2. The importance of prematurity as a causative factor in cases of rickets must be borne in mind, and given more weight than has perhaps been the rule in the past.

3. Tetany is due to low calcium, and may occur either separately or as a complication of low calcium rickets.

4. Rickets occurs in both the breast and bottle fed, and other factors beside diet must be taken into consideration when seeking the etiological factor.

5. The parathyroids must not be overlooked as a causative factor in tetany.

6. Every mother should be urged to nurse her baby for nine months at least, with the addition of fruit juice from the fifth month on, and the only diet to be considered when this is impossible is cow's milk, in cases of rickets.

7. When using cow's milk certified milk should be given the preference, when obtainable, otherwise pasteurized milk should be used reasonably promptly after pasteurization and kept on ice in the meantime.

8. The testing of whole blood or blood serum for its calcium content may readily be performed in any laboratory, and the performance of this test is of sufficient value to warrant its being done in all cases of suspected rickets or tetany, or both, in order that one may know whether it is a question of administering phosphorus or calcium to the limit. By this means many cases of tetany will be prevented, both as a complication of rickets and as a disease *per se*.

9. The correct treatment of these cases means so much, not merely so far as life is concerned, but more particularly the prevention of deformities, that a day or two's delay while awaiting the results of the calcium test is time well spent.

10. Codliver oil, with phosphorus or calcium, or both, is the only treatment to be considered, outside of diet and hygiene, and the most important point in the use of these remedies is to be sure to give enough of the one that the child's system craves, the diminution or absence of which has probably been the etiological factor in causing the symptoms.

The Instability of Adolescence and Its Treatment from the Endocrinological Viewpoint

By E. BOSWORTH McCREADY, M.D., F.A.C.P.,
Pittsburgh, Pa.

From the viewpoint of physical and mental health there is no more important period in the person's existence than that of puberty, involving as it does most radical changes in all physiological functions. As stated by Hall (1) "Adolescence is a new birth, . . . The annual rate of growth in height, weight, and strength is increased and often doubled, and even more. Important functions, previously non-existent, arise. Growth of parts and organs loses its former proportions, some permanently and some for a season. Some of these are still growing in old age and others are soon arrested and atrophy. The old measures of dimensions become obsolete, and old harmonies are broken. The range of individual differences and average errors in all physical measurements and all psychic tests increases. Some linger long in the childish stage and advance late or slowly, while others push on with a sudden outburst of impulsion to early maturity."

Physical and mental breakdown in youths of both sexes from twelve to eighteen years of age are common and health impaired in some degree is so frequent as to require no emphasis. Every year more than twenty thousand adolescents are afflicted with dementia precox and a considerable proportion of suicides in this country are in children of school age. Goitre, and other forms of endocrine disturbance, chlorosis, and other anemias, epilepsy, tuberculosis, gastric and duodenal ulcer, nephritis, various neuroses, and a host of minor maladies are likely to make their initial appearance at this time or to become exaggerated to an alarming degree. Normally the healthy human being passes through the physiological changes incident to pubescence without mishap and with only those milder manifestations of imbalance inevitable to such comparatively sudden changes in the economy. However, we must face the fact that a large proportion of the population are not normally healthy, and that constitutional inferiority is rather the rule than the exception. Further, the stress and strain of modern life tends to increase deficiencies which might otherwise be negligible.

It is not my intention to discuss in this paper gross abnormalities of mental and physical deviation but merely to call attention to some of the milder manifestations of imbalance occurring at the adolescent period, which are met with frequently by every physician, and which deserve more than the indifference usually accorded them. The instability of adolescence which is sufficiently grave to warrant our attention usually has its beginnings early in the life of the individual through causes which may be hereditary, acquired or a combination of both. Thus as etiological factors there may have existed: 1, defects in the chromosomes of the ovum or spermatozoon of parents; 2, toxemia in the parent, or parents, affecting the ovum or spermatozoon, or both, resulting in a defective impregnated ovum or germ; toxemia in the mother, or poisoning of the germ because of local disease in the endometrium, or insufficient nutrition of the developing ovum, or unfavorable environment in postnatal life leading to disease, to malnutrition or to toxemia; 3, a combination of hereditary and environmental causes, which is perhaps the most frequent. (Noble).

Thus vitiating influences interfering with normal cell development and with the natural force of growth become aggravated because of the intimate interrelation and interdependence of the various systems of body cells, among the most important of which are those initiators and regulators of correlative growth—the vegetative nervous system and the ductless glandular systems, and through the formation of a vicious circle further impairment of somatic and functional integrity results.

Most significant phenomena at this period are those relating to the endocrine glands. Coincident with the involution of the thymus occurs increased functioning of the thyroid, the pituitary, the chromaffin system and the gonads. Under normal conditions these act in harmonious equilibrium and through the correlative activation of all bodily processes the child metamorphoses into youth gradually and uneventfully. But, as a chain is as strong as its weakest link, so is the adolescent as strong as his weakest organic entity, whether it be nervous, endocrine or other. The strain of puberty is then all that is necessary to bring out inherent inadequacies.

As an access of function on the part of the endocrine system is the exciting cause of the phenomena of adolescence it is natural that many of the abnormalities incident to this period should be attributable to irregularities of function in these important organs. Not only may somatic and physiological anomalies have their origin in the endocrine organs but also behavioristic anomalies as well. For as Cushing has stated (2) ". . . it is quite probable that the psychopathology of everyday life hinges largely upon the effect of ductless gland discharges upon the nervous system. This is particularly worthy of consideration in the study of child psychology in its relation to puberty and adolescence, especially in those individuals in whom there is some underlying, possibly inherited, functional deviation in the chemistry of the internal secretions."

For a number of years, since Charles P. Noble, whom most of us know as a brilliant gynecologist of a few years past but possibly few know as a deep student of genetics, of biology and the phenomena of degeneration, first impressed it upon my mind, I have emphasized the importance of an underlying constitutional hypoplasia in the etiology of developmental defects in children. In a more or less general hypoplastic constitution there is likely to be considerable involvement of the glandular structures, the symptoms of which are likely to become most manifest at puberty. All endocrine irregularities manifesting themselves at puberty do not, however, have a basis of constitutional inferiority, for as Hoxie (3) says, "All endocrine anomalies are not congenital but many of them are the results of accidents occurring in adolescence and early adult life."

A syndrome which even in its frequently met milder forms is responsible for much instability at this time is one of which the manifestations are soft velvety skin, retarded appearance of axillary and pubic hair, delayed development and differentiation of genital system, disproportionate skeletal growth. These patients are fatigued easily, are subject to dyspnea on exertion, are likely to faint and collapse in critical situations, and are liable to syncope and even death under narcosis, from fright, and as the result of profound exhaustion. They are subject to urticaria, asthma, hay fever, acidosis and enuresis, are unduly vulnerable to infectious diseases, especially to tuberculosis, and are frequent sufferers from nephritis and diabetes. An existing tendency toward stammering or stuttering becomes aggravated at this time, and epilepsy frequently makes its appearance during this epoch in these subjects.

Bartel (4) observes that suicide is a not infrequent termination to their lives. The behavioristic irregularities are founded upon the easy fatigability, the headaches and other organic pain sensations and from the sense of inferiority developed as a result of appreciation of their own physical and functional anomalies. The mental capacity is often decidedly subnormal though this is by no means a constant concomitant, as a high degree of intellectuality is often found especially in the milder grades.

Such patients are likely, however, to be unstable, eccentric, and incapable of sustained application, and so become lax in their school work, do not take part in the activities of their comrades, and become careless and untidy about their persons. Feeble emotional inhibition is common and moral inferiority may be shown by pathological lying, stealing, and other traits. My experience with these persons in juvenile courts has shown me that many youthful delinquents are of this type and that usually they come into conflict with the law more through the influence of a stronger personality than through their own initiative. Sometimes, however, aggressive persons are met with in whom the sense of inferiority seems to drive on to extremes of action in an endeavor at compensation. Among sexual offenders the individual of this type is usually the passive instrument, in the case of the female easily seduced not by reason of strong libido but because of weak resistance and lack of ethical appreciation. Both sexes are prone to become the victims of sexual degenerates, especially because of their bodily configuration being especially attractive to inverts.

While indications of anomaly of the thymus are frequently apparent in these cases, the anomalies of development have been ascribed to deficiency of the gonads, underactivity of the adrenals, and of the pituitary. Timme (5) contends that the syndrome is pluriglandular, dependent in a large degree upon deficiency of the chromaffin system. In this I agree and am also inclined to believe that the enlarged and persistent thymus may be a factor only through reactivation (Hoxie) of the thymic parenchyma. This reactivation may be secondary to disturbance in endocrine equilibrium rather than causative.

With the approach of puberty the thyroid becomes more active, both as a cause and as a result of the increased metabolic demands of the economy. Upon this increased activity depends, in large degree, the sexual differentiation and maturity of the individual. To an extent hypertrophy at this time is physiological and normal, giving to the young girl the full round throat, esthetically desirable, and to the boy an added prominence to the region of the enlarging larynx. Both sexes at this time are thyroid conscious, of constricting bands about the neck. Hence the low neck attire of the flapper and the sport shirt of the hobbledehoy. In the organically inferior the thyroid is either inherently inadequate to the increased demands upon it, or if normal must compensate for the insufficiency of other structures; in either case it may become overactive. Irritating factors of various kinds, toxic, emotional and reflex, may also cause thyroid hyperactivity.

The manifestations are those of an overdrive-excitability, overactivity with intervals of fatigue, emotivity, in fact all the manifestations of hyperthyroidism found in the adult but modified in certain aspects because of the lesser adjustability of the subject. These causes are often difficult problems in home and school and require careful and judicious handling. They form a fairly large proportion of juvenile delinquents, are aggressive, impatient of restraint, are gang leaders, and disturbing elements generally. They are often hypersexual and thus prone to sex delinquencies of an aggressive type. Thus in discussing the premature eroticism leading to sexual misdemeanors I have elsewhere stated (6) that in making examinations in juvenile courts I have been struck by the fact that practically without exception all girls charged with sexual offenses have enlarged and overactive thyroids. Just within the last few days I have seen a colored girl, aged twelve, brought into a juvenile court because of nymphomania and seduction of other children of both sexes to unnatural sexual practices who has a marked hyperthyroidism, enlarged thyroid, pulse 150, tremors, slight exophthalmos.

In more severe degree of organic insufficiency of the thyroid or when the gland has been crippled by an acute toxemia earlier in childhood, or by a milder long continued toxemia, it fails to meet the increased functional demands and hypothyroidism results. These subjects become more or less dull and lethargic, are unable to keep up with their classes, fatigue easily, are moody, introspective, and may put on weight. In girls the menses are delayed, irregular and painful. These subjects are fretful and querulous and incapable of sustained effort.

True dystrophia adiposogenitalis is usually due to tumor or injury to the pituitary and is characterized by genital aphasia, adiposis and deficient skeletal development. However, minor forms are frequently met in which the pituitary deficiency is transitory or which respond to treatment with subsequent normal development. These subjects in contradistinction to the case with organic impairment are often alert mentally, goodnatured and physically active but may be defective in ethical appreciation. One of my patients obtained large sums of money on several occasions by forgery, but after custodial care in an industrial institution under favorable hygienic conditions with pituitary feeding the hypopituitary manifestations disappeared and in several years there has been no delinquency.

Tucker (7) in a most comprehensive paper in 1918 called attention to the psychic manifestations of pituitary anomaly in adolescents. Eunuchoid types in mild degree are met with in adolescents of both sexes. These exhibit no special behavoristic characteristics other than asthenia and immaturity of judgment.

Since the phenomena of adolescence are intimately concerned with the sexual maturation of the person it is but natural that manifestations referable to the reproductive organs and functions should occur at this time. Mention of such anomalies has already been made in connection with disturbances in other endocrine organs and in fact so intimate is the relationship existing between the gonads and the rest of the endocrine system, the thyroid, pituitary and suprarenals being responsible for development and subsequent activity, and the thymus, and possibly the pineal, for restraint of precocity, that discussion of the former structures can hardly be separated from the former—at least in a paper of the present scope.

Functional hypoadrenia ("a symptom complex of deficient activity of the adrenals due to inadequate development, exhaustion by fatigue, . . . or any other factor, . . . capable of reducing their secretory activity." Sajous) is frequently found in adolescents, and is marked by sensitiveness to cold and cold extremities, hypotension, weak heart action, anorexia, anemia, constipation, asthma and other manifestations of hypersensitiveness, and by psychasthenia. These patients are unable adequately to meet the demands of ordinary life. Fatigability is a manifestation of the condition and exertion or sustained effort increases the adrenal depletion. They are emotional, crave excitement, but are fatigued by excitement. Often clever students, their work is sporadic and superficial. Their enthusiasms are intense but shortlived, but may be revived after sufficient periods of rest. They are unduly susceptible to infections and toxemias, and to reflex irritations.

The treatment of the manifestations of instability in adolescence may be divided as follows: 1, Preventive; 2, hygienic; 3, medical.

PREVENTIVE.

Could we begin our treatment with the grandparents our results might be more brilliant, for in many instances we are dealing with the end results of a long line of perverted physiology, aggravated by extraneous, often preventable, pernicious influences. However, as our patients of the present generation are the grandparents of the future the situation is not without hope. Prenatal hygiene and treatment of the expectant mother, in selected cases by endocrine therapy, offers encouraging results. Proper attention to nutritional needs during infancy and childhood (McCarrison (8) has observed, in the course of feeding experiments in animals, that malnutrition from insufficient or improper diet, gives rise to enlargement of the adrenals and sometimes of the pituitary body with atrophy of all other endocrine structures) fresh air, exercise, clothing, sleep, etc., avoidance of undue fatigue and strain, shielding from infection and all measures which may be included under the term health culture have their influence for good in preventing and combating endocrine instability.

The medical treatment of chronic states of ill health, of anemia (of the greatest importance in my opinion), malnutrition, etc., is most necessary. Marine and Kimball (9) have shown what can be done in childhood in the way of prevention of simple goitre by the administration of three to five mg. of iodine twice weekly over a period of one month and repeated twice yearly. Of 2,190 school girls taking two gm. sodium iodide twice yearly in only five thyroid enlargement developed, while of 2,305 not taking the treatment in 495 enlargement developed. Of 1,182 with goitre taking the treatment 733 thyroids decreased in size; of 1,048 with goitre not taking the treatment 145 decreased in size.

During acute disease and during convalescence due consideration should be accorded the possible deleterious effects of the disease processes upon the endocrine system, and the proper steps taken to combat these effects. Care should be used that the therapeutic measures utilized in the treatment of the disease shall not harmfully affect the endocrines. I am convinced that overzealous use of serums, vaccines, and other foreign proteins, and the intravenous injection of chemical substances is sometimes followed by permanent damage to the endocrine system and to the nervous system, as a result of anaphylaxis and allergy.

The hygienic supervision of the unstable adolescent is of the utmost importance, probably of more importance than more strictly medicinal treatment. Modern life with its fetish of strenuosity exposes the youth to the very influences which are most inimical to his proper development. Arduous school work with long hours, lessons to be prepared at home, competitive sports without proper supervision, movies, jazz, erotic literature, joy rides, inadequate meals, and other factors all tend to increase existing instability and to establish instability in the organically stable. Modern usage takes no account of the phenomena of normal adolescence, of the lassitude of mind and body alternating with periods of undue activity, the emotional unrest, easy fatigability, the egoism, the need for much sleep, much food, and much fresh air and sunshine. The adolescent should be carefully studied in regard to his existing capabilities and his duties and activities modified as required. Except where actual hyperthyrodism exists, in which case complete rest is needed, the youth will be benefitted by active outdoor exercise, his school work should be curtailed if necessary, his hours of sleep should be long, his meals bountiful with due regard to the craving for sweets, his skin kept active, and he should be encouraged to find relaxation in activities which interest without undue emotional excitement.

The psychic life of the adolescent is full of conflicts, complexes, and suppressions. Proper physical hygiene and sympathetic understanding on the part of parent, teacher or physician are the best methods to bring about adjustment.

Though normally "youth is a disease which cures itself" the class of cases which we have been considering require something more than neglect or even ordinary hygienic care. Anders (10) impresses the fact that "we must not be unmindful of minor degrees or earlier stages of dysfunction, where it is difficult in the extreme to recognize any of the features which ordinarily make up the characteristic syndrome. These, however, call for and are readily amenable to appropriate specific organotherapy." The first step in treatment is the removal of all possible sources of focal infection and reflex irritation. The anemia, present in the majority of cases, must be adequately treated. In girls the anemia is often chlorotic in type. The above is often sufficient to bring about a satisfactory state of endocrine, nervous and emotional equilibrium with the gradual amelioration of untoward symptoms. It often requires a nice discrimination to determine whether symptoms of imbalance are manifestations of normal or of perverted physiology. The routine administration of organic products is reprehensible and likely to convert normal physiological processes into abnormal ones. These substances are, however, of very great value when indications for their use actually exist.

In deficiency of the chromaffin system suprarenal and pituitary substance are of value. I prefer the whole pituitary gland given in small doses and increased gradually. The action, when the basal metabolism rate is low, is enhanced by the addition of thyroid one one hundredth to one tenth grain. In girls I also give ovarian substance. Where thyroid inadequacy exists, with or without hypertrophy, thyroid substance or extract, or thyroxin is given with advantage. With a drug as potent as thyroid the same care should be taken in administration as with arsenic, belladonna and other toxic drugs. Pollock (11), collaborating with me in a paper to be published, has called attention to the dangers of unchecked thyroid therapy and also to the advantage of therapeutic control through periodical basal metabolism estimations.

CONCLUSIONS.

1. The period of adolescence is, in both sexes, a time of unusual physical and mental stress, tending to increase inherent weaknesses and to initiate organic and functional anomalies.
2. The endocrine system, because of its intimate concern with growth and development with metabolism and with the phenomena of sexual maturity, is particularly prone to disturbance of function.
3. The endocrine implications may manifest themselves in many and diverse ways, requiring careful analysis for detection and for correct evaluation of their relative importance.
4. Well advised prophylactic and hygienic management and, in properly selected cases, rational therapeutic intervention will accomplish much in the way of prevention and correction of anomalies of physical and mental function during this important epoch.

Foreign Proteins in Prophylaxis and Therapeutics

By FRANCIS E. STEWART, M.D., Phar. D., F. A. C. P.
Philadelphia.

To obtain a proper perspective of our subject it is necessary to refer to the socalled allergic state and to immunity conferred by an attack of infectious disease or obtained by vaccination.

THE ALLERGIC STATE AND IMMUNITY.

The word allergy means altered reaction. A change is produced in the body of the vaccinated individual by smallpox vaccination. The power of quick response has been conferred upon the body cells When an individual has been successfully vaccinated for the first time the well known vesicle, surrounded with an inflammatory areola, appears after a distinct period of incubation. The vaccinated person is now immune to smallpox for a period of several years during which time the immunity gradually loses its potency. If, during this period, the immunized person is revaccinated there appears to be no reaction; but careful observation will show that this is not the case. There is a response, but the reactive phenomena are so mild, and the changes occur so rapidly, that they usually pass unnoticed.

This peculiar change in reaction was noted by Jenner but soon forgotten. Later Brice observed the same phenomena, but it was not until the researches of Von Pirquet again brought the subject into prominence that it attracted serious attention. According to the present view of the allergic state as an explanation of immunity, the body cells are sensitized by the first vaccination and are thus in position to respond more promptly when again attacked by the same microbe and defend the body by producing the antimicrobic substances to which immunity is due.

WHAT IS A VACCINE?

The term vaccine is derived from the Latin *vaccinus* of or from cows (*vacca* a cow). It is applied correctly to the virus of vaccinia, or cowpox, used in vaccination. Of late years it has acquired a secondary meaning and is now also applied to any substance for preventive inoculation. Macfarland (*Cohen's System of Medicine*) suggested the name bacterin as more appropriate than vaccine for bacterial cultures used for inoculation. At the suggestion of Dr. S. Solis-Cohen, Philadelphia, I used it for the first time in current medical literature in a paper read before the American Therapeutic Society, in Washington, D. C., 1910.

The term vaccine as now used by immunologists applies to any bacterial product used for preventive or therapeutic inoculation. It is defined by some authors as a disease virus so modified as to destroy its power of infection, but not so altered as to destroy its immunizing properties. Smallpox vaccine is smallpox virus modified by passage through the bovine species. Typhoid vaccine is typhoid bacilli modified by heat or antiseptics.

Victor C. Vaughan speaks of infective agents (the known infective agents are bacteria, protozoa, moulds, and yeasts) as living proteins, and points out that their pathogenicity is due to their power of growing and multiplying in the living body. Immunity is due to the specific power of the body cells to defend the living body from the attacks of infective agents by the production of specific antimicrobic substances. As stated by Hektoen (1), "Immunity against infection may be regarded as merely a special instance of the power of the body, by special mechanisms, to rid itself of harmful foreign proteins."

THE DOCTRINE OF SPECIFICITY.

The immunity acquired by an attack of an infectious disease is *specific*. Recovery from smallpox does not confer immunity to typhoid fever; neither does recovery from typhoid fever confer immunity against smallpox. And the same principle of specificity applies to vaccination against these infectious disease, that is, smallpox and typhoid fever, with the appropriate vaccine.

In addition to their specific properties, vaccines, in common with all foreign substances, when introduced into the living body cause defensive reactions. These reactions are merely Nature's efforts to get rid of the harmful substances. But these defensive reactions are not specific. A wound in healing not only rids itself of the bullet that produced it, but also rids itself of the extraneous substances carried into the wound by the bullet.

NONSPECIFIC PROTEINS AND THEIR VALUE AS THERAPEUTIC AGENTS.

More recently certain nonspecific proteins have come into vogue as therapeutic agents. They are of no specific value. Only specific proteins are capable of immunizing against infectious diseases. Injections of milk, normal horse serum, or other nonspecific protein are of no specific value in treating typhoid fever, whooping cough or pneumonia. Yet competent observers find nonspecific proteins of therapeutic value. How is this to be accounted for? The answer is to be found in the fact that reactions produced by foreign substances when introduced into the living body not only rid the body of one foreign substance but also rid it of other foreign substances as well. This becomes the more apparent in the light of experiments made by several medical scientists who have injected various kinds of foreign substances intravenously and observed the same phenomena. For example, the intravenous injection of colloidal metals (colloidal solutions of metals), as well as various nonspecific proteins, has been effective in aborting infectious arthritis. The best results are obtained when sufficient doses are injected to cause reactive phenomena characterized by a chill, followed by high fever, and followed, in turn, by a sweating stage.

All of these foreign substances, when introduced into the body, stimulate the body cells to get rid of them, and, in so doing, aid the body to get rid of disease producing microbes if they are also present. But these nonspecific reactions confer no immunity to another attack of the same disease.

THE SUPERIOR VALUE OF SPECIFIC PROTEINS.

As stated by Hektoen, from whom I have already quoted: "The production or heightening of the natural immunity possessed by every person against the infectious diseases is one of our chief and most potent measures in their prevention and cure. It is now quite generally accepted that antitoxic and antimicrobic effects occurring during the process of immunization depends upon the presence within the body of substances of *limited specific affinities*—antitoxins, opsonins, immune bodies or amboceptors, that are produced by the body cells." I have used italics to emphasize the fact that the body cells are incapable of producing antibodies specific to infectious diseases unless *specific* bacterins are used, that is, bacterins containing the bacteria corresponding with those causing the disease.

The superior value of specific proteins, therefore, is apparent. They possess all the nonspecific value of nonspecific proteins, and the great advantages resulting from their specificity.

Bacterins, or vaccines, therefore, owe their therapeutic properties to their power of stimulating the body cells to defensive reaction—a property shared by foreign substances generally when introduced into the body—and also to the power of stimulating the body cells to produce specific antibodies, and so sensitizing them at the same time that they become allergic and thus prepared to respond promptly when again attacked by the same microbe.

Referring to the experiments upon which the evidence that nonspecific substances introduced into the body possess therapeutic value is based, an editorial writer (in the *British Medical Journal* if my memory is correct) says that the stimulating effect of their presence furbishes the defensive mechanism of the body and thus aids in throwing off the infecting microorganisms when used in the treatment of infections. Or, as expressed more happily by Gellhorn (2), "all cells of the body feel this rejuvenating influence, but none more so than those cells which have been weakened or paralyzed by infection. These cells seem to obtain a new lease of life; some of their normal vigor returns and their natural means of defense becomes reassembled." This is Gellhorn's verdict founded upon his use of milk in the treatment of pelvic infections. A similar verdict would doubtless have been given if a specific bacterin had been employed, and, in addition, a certain amount of insurance against subsequent attacks might possibly have been secured.

WRIGHT'S CHANGE OF VIEW REGARDING SPECIFICITY.

Sir Almroth E. Wright, the "father of bacterial vaccine therapy," no longer believes that bacterins, to be of therapeutic value, must be strictly specific. He no longer teaches that "microbic infections can be warded off only by working with homologous vaccines, and that we must in every case before employing a vaccine therapeutically, make sure that the patient is harboring the corresponding microbe." In his lecture on the Lessons of the Great World War (3), delivered before the Royal Society of Medicine, February 25, 1919, he said "it is of fundamental importance that we discard the confident dogmatic belief that immunization must be strictly specific." However, in saying this he made it manifest that he had no intent of discarding his belief in the doctrine of specificity. He teaches that bacterial vaccines, when used therapeutically, not only possess the power of specific immunizing response, but also possess what he calls collateral immunizing properties.

AUTOGENOUS VERSUS STOCK VACCINES.

Contrary to the belief of certain of his followers, Wright never taught the exclusive use of autogenous vaccines. On the contrary, he used stock bacterins as well as autogenous bacterins from the beginning of his career as an immunologist. It was in using and comparing the results obtained in the use of autogenous and stock vaccines that he was led to conclude that their efficiency was not exclusively due to specific immunizing response. He said, in his lecture (3), "Among, I suppose, many thousands of patients treated by vaccine therapy in private and in hospital, it happened every now and then that a patient was treated with a vaccine which did not correspond with his infection, and that patient indubitably benefitted. Again, it was not an uncommon experience for the subjects of a very chronic infection (such as pyorrhea) who were first treated with stock vaccine, and afterward with an autovaccine, to assert that they derived more benefit, and to ask to be put back upon treatment by the stock vaccine. We should proceed upon the principle that the best vaccine to employ will always be the vaccine which gives on trial the best immunizing response against the microbe we propose to combat."

MIXED VACCINES.

Referring to mixed vaccines, Wright said: "They should be recommended in cases where from the outset there is very little response from the homologous vaccine, and also where, as in very long standing cases of tubercle or streptococcus infection, the power of direct immunizing response is becoming exhausted." Dr. A. P. Hitchens, in a paper read before this society several years ago, called our attention to the fact that "Nature is an unscientific jade" and cures mixed infections with mixed bacterial treatment. In a mixed infection Nature does not single out the initial invader and confine her attention to its destruction, but has taught the body cells to repel the invasion by producing antimicrobial substances for destroying all of the germs taking part in the infection.

THE USE OF BACTERINS IN ACUTE INFECTIONS.

The old idea that bacterins are dangerous in acute infections still prevails with some physicians. Wright has been combatting it from the beginning of his advocacy of bacterins as therapeutic agents. In his lecture before the Royal Medical Society, just quoted (3), he found it again advisable to answer those who criticize the use of bacterins in the treatment of acute infections by putting forward the theoretical argument that "to inoculate microbes into the already infected system would be as illogical as to instil further poison into an already poisoned system." In answer to these objectors Wright calls attention to the fact that the body should not be visualized as a single and undivided unit. One region of the body may be making immunizing responses to an infection while the other is inactive. "For instance, in the stage of incubation it is presumable only the region which is actually harboring a microbe" is responding, "and in the stage of generalized infection it is presumable that the entire body is incited to respond. And, again, in localized infections we may—making some reserves—assume that we have only localized infection. Placing ourselves at this point of outlook, therapeutic immunization will, it is clear, be theoretically admissible so long as there remains in the body any part which is not already making its immunizing response. And the program of therapeutic inoculation would accordingly consist in exploiting, in the interest of the infected regions of the body, the immunizing response of the regions which are not infected."

Whether or not Wright's ingenious explanation in answer to his critics is accepted, the fact remains that some of the best reports regarding the efficacy of bacterins as therapeutic agents come from physicians who are using them in the treatment of acute infections. E. C. Laferty (4), of Louisville, Ky., in referring to differences of professional opinion on the subject says: "But experience is our best teacher," and "in therapeutics careful clinical observation under the use of certain therapeutic measures is our safest and surest guide toward therapeutic progress and the lessons taught by experience are often just the reverse of what was expected." He was one of those who "had accepted the belief that, in the treatment of extensive acute infections with high temperature, vaccines would be theoretically contraindicated," but he had "found the reverse to be true; that instead of being contraindicated our very best results are obtained in just this class of cases." He believes that a toxic condition as the result of infection does not necessarily imply that the substances which are responsible for the toxemia are of the kind which will favorably influence the resistance of the patient, and that the essential requirement under such conditions is the immediate application of a stimulus which will arouse the defensive forces for the development of suitable antibodies.

Laferty further states "that bacterial vaccine injections do not increase the toxicity of the patient, when given in extensive acute infections, which is readily determined by a careful observation of the temperature curve and the pulse rate. When given under high temperature conditions no appreciable rise in temperature will follow a vaccine injection, nor do any other unfavorable symptoms develop which can be ascribed to the vaccine injection. But, on the contrary, as a rule it will be found that the temperature will come down, the pulse will improve, and other toxic symptoms will start to abate within twenty-four hours provided the proper vaccine in a sufficiently large dose has been given before the infection has advanced sufficiently to cripple the responses of the patient. Usually this will hold good during the first few days of the infection; but the best results are obtained if the vaccine is given soon, within a day, after clinical symptoms show the presence of an active infection."

The author goes on to emphasize the importance of early and frequent doses. He says: "In severe acute infections where germ development is extensive, antibodies are used up rapidly. A small area of tissue where the vaccine was injected may become actively engaged in the production of antibodies;

but, as a result of toxic materials distributed through the system from the infecting organisms, these activated cells may in time become fatigued in this capacity; then, after a short spell of clinical improvement, often so dramatic that one is inclined to think the trouble is over with, and the case is allowed to drift along until within three or four days the condition becomes just as bad as before the vaccine was given, and not uncommonly when this condition develops the vaccine will not produce the striking results that the first dose did; meantime, as a result of accumulated toxemia from the progressing infection, the cells of the body have become less responsive to the antigenic influence of the vaccine. For these various reasons it is very important that inoculations should be made at comparatively short intervals in extensive acute infections, so that another immunizing response will have time to develop from newly involved tissue at the site of injection before the immunizing influence from the previous injection has had time to wear off. Clinical experience indicates that this is best accomplished by giving the vaccine at daily intervals until the temperature shows a distinct tendency to remain down, but it is never wise to give less than two or three injections at daily intervals, even if the temperature does come down to normal meantime. After a normal temperature is obtained inoculations should be made at two to four day intervals until convalescence is complete. In extremely bad cases it is advisable to give the vaccine twice daily until the very severe symptoms are brought under control."

The system of doses recommended above is in marked contrast to that originally advocated by Wright (5). A dose table was published soon after Wright's papers first appeared, said to have been devised by Wright himself to designate a safe arbitrary initial dose for each bacterin; subsequent doses to be increased gradually. If, following any dose, a clinical reaction should occur, characterized by rise in temperature and aggravation of local symptoms, a general malaise, etc., it was directed that the same or a smaller dose should be given. In regard to frequency of dose, it was directed, as a general rule, that the intervals between doses should usually be from two to four days in acute cases, and from two to seven days in chronic cases. As certain persons manifested hypersensitiveness to bacterial proteins of various kinds, resulting in severe reactions even when small doses were employed, some physicians were in the habit of commencing with a minute dose as "a feeler" and then proceeding in the regular way if no special sensitiveness appeared to be present. It is evident that the two systems of doses are capable of producing very different clinical results, and that tests should be made, under proper controls, to ascertain which system is preferable.

IMPORTANCE OF EARLY TREATMENT.

W. H. Wynn, whose contributions to the subject of bacterin therapy are widely known, urges (6), that with certain acute infections "there is a margin of time during which it is possible by suitable intervention to cut the disease short." He says: "If a *laissez faire* policy is adopted and this opportunity passes, the patient's fate, in so far as it depends upon a conflict with the invading germs, is committed to chance; that with such infectious diseases as measles and scarlet fever [where the cause has not been determined—*author*] we cannot at present offer anything better than the expectant method; but with acute lobar pneumonia, influenza, cerebrospinal fever, typhoid fever, whooping cough, and diphtheria, specific treatment can be applied as soon as diagnosis is made out." Referring to acute lobar pneumonia, the author says: "The use of a suitable vaccine during the first few hours after the onset of the fever gives brilliant results. With each hour that passes success is less easily obtained. There is an exact parallel with the results of antitoxin treatment of diphtheria or the operative treatment of appendicitis in this respect."

IMPORTANCE OF ADEQUATE DOSES.

Wynn emphasizes the importance of adequate doses. The bacterin was a polyvalent bacterin containing equal number of pneumococci, streptococci and influenza bacilli. He recommended the following doses: "For an adult man, eighty to one hundred millions; for an adult woman, sixty to eighty millions; for a child of twelve to fourteen, forty to fifty millions; for a child of two to three years, ten to twenty millions."

The author says: "I have several times repented of giving too small a dose and have only obtained an effective response on increasing. . . . In influenza I have not ventured above one hundred millions, although in acute pneumonia I have given above one hundred millions."

Dr. Wynn's paper is a very comprehensive report of experience in the treatment of a large number of patients with acute infections. It contains many important statistics, is illustrated by clinical charts, and is worthy of thoughtful consideration.

SENSITIZED BACTERIAL VACCINES.

A sensitized bacterial vaccine, as defined in Dorland's *Medical Dictionary,* is "an emulsion of a bacterium which has been treated by the application of the corresponding immune serum." Since, in the case of immune serum, a rapid (immediate) but transitory immunization is possible, and by the use of bacterins a slower but more permanent immunity is brought about, a combination of the two agents was sought.

Ehrlich and Morganroth (7) demonstrated in 1899 that bacterial cells absorb their specific amboceptors (antibodies) from immune serum. In 1902, Besredka (8), proposed a new method for preparing sensitized vaccines by exposure to immune serum. Besredka's conclusions at that time were as follows: "Immunizing with serum (passive immunity) is rapid and inoffensive, but fleeting. The immunity conferred by the bacterial bodies themselves is of longer duration but is established only after eight to twelve days, during which the resistance of the organism is enfeebled, and the injection is accompanied by local and general symptoms. The immunity conferred by sensitized vaccines (antiplague, anticholera, and antityphoid) is of longer duration. It is established in from twenty-four to forty-eight hours, during which the organism is reinforced, and the injection is not accompanied by appreciable local or general phenomena."

According to Besredka, a view concurred in by

Gordon (9), "the object of sensitizing bacteria is to promote their phagocytosis, and the effect of sensitization is to accelerate the immunity by shortening the preliminary work of the phagocytes and causing them to deal at once with the endotoxin of the invading bacteria."

Whether Besredka's and Gordon's conception of the mechanism of the action of sensitized bacteria is entirely correct, in assuming that immediate phagocytosis is the determining factor in the rapid production of immunity and the neutralization of the infecting bacteria, or their products, the observations of a large number of workers, both in experimental animals and the human, show that reactions, both local and general, are eliminated or much diminished.

The observations on experimental animals in the research laboratories by Corsa, Craig, and Richards working in cooperation with Huntoon (10) show that a properly sensitized bacterin carries with it a certain definite antibody charge, some of which, upon injection into the animal body, is promptly set free and confers a degree of immediate passive immunity upon the recipient. This passive immunity commences at once to decrease in potency, but persists during the period of the socalled negative phase of Wright, and continues until the tissues commence to respond to the stimulation of the injected bacteria, producing new additional antibodies which now take the place of the injected antibody, so that the injection of such a sensitized bacterin combines the advantages of some immediate passive immunity with an active immunity which persists some time.

ADVANTAGE OF SENSITIZED BACTERIAL VACCINE OVER BACTERIN PROPHYLAXIS.

The preceding statement refers to the effect of a single dose of sensitized bacterial vaccine administered to an animal for the purpose of observing the character of the immunizing response. In the practical application of sensitized bacterial vaccine for combating an epidemic of typhoid fever, for example, the method is to administer three to five gradually increasing doses at intervals of three to seven days. Each dose increases both passive and active immunity—the short intervals between doses, by setting free repeated charges of antibodies, augmenting the passive immunity, the injected bacteria repeatedly stimulating the body cells to produce antibodies, thus increasing and building up the active immunity. This method is in marked contrast to the one employed in immunizing with three doses of unsensitized bacteria at ten day intervals. No immunizing response follows the first dose until the lapse of six to eight days; no passive immunity is produced for the protection of the vaccinated individual during the interim, nor for additional protection during the interim between the second and third doses. The advantage of sensitized bacterial vaccine over bacterin in combating an epidemic of typhoid fever is thus apparent.

ANTIBODY SOLUTIONS.

During the investigation by Huntoon on the separation of antibody from sensitized bacteria it was discovered that the injection of sensitized organisms into animals was followed by an immediate passive immunity, varying with the dose and amount of antibody set free in the animal. The problem suggested itself to separate and secure antibodies in solution outside of the animal body.

Huntoon continued his investigation on the production of antibody solutions free from serum protein, that could be employed therapeutically. In this he was finally successful. The method discovered was applied to the production of pneumococcus antibody solutions, as follows:

Horses were injected at regular intervals with emulsions of Types I, II and III pneumococci. The serum, after a number of injections, developed protective antibodies.

To this serum was added an equal volume of a heavy emulsion of living pneumococci, Types I, II and III. The mixture was placed at 37° C. for twelve hours, and then centrifuged. The sediment was washed with salt solution to rid it of horse serum. The washed sediment was emulsified in salt solution containing 0.25 per cent. sodium bicarbonate and heated to 55° C. for from thirty minutes to one hour. This caused disassociation of the pneumococcus (antigen) and antibody. The mixture was then centrifuged, and the supernatant fluid removed, chilled, recentrifuged, and finally filtered through a filter candle. The final solution, which contained only 0.035 mg. of nitrogen to the cubic centimetre, was, in many lots prepared by this process, able to protect mice against as many fatal doses of pneumococcus Types I, II and III as the orginal serum from which it was made (11).

When the research on pneumococcus antibody solutions had reached the stage where reasonable amounts could be produced, having a potency against the three fixed types of pneumococcus, approaching that of immune serum, clinical cooperation was secured for the testing of the solutions.

Such material, however interesting from the academic viewpoint, can only be useful if clinically available, and a complete and unbiased test could be the only method of determining its value.

The laboratory and clinical research were entirely separated, the material being turned over to the hospitals in the quantities requires, the physicians in charge agreeing to report on the cases in which it had been used, whatever the result.

OTHER FOREIGN PROTEINS.

Foreign proteins play an important part in the etiology of hay fever, bronchial asthma and various cutaneous diseases. Success in this field attending their use as diagnostic, prophylactic and therapeutic agents is attracting considerable attention in medical circles both in this country and abroad. Their employment rests upon the same principle as those upon which the use of the protein substances already referred to is based, namely, the principle of antigen-antibody reaction.

These tests were conducted in the wards of Bellevue Hospital, New York, by Dr. Russell L. Cecil and Dr. Carl Neil Larsen, working under a cooperative arrangement between Bellevue Hospital, the Influenza Commission appointed by the Metropolitan Life Insurance Company, Cornell University Medical Department, and the United States Public Health Service. Tests were also conducted in the wards of the New York Hospital by Dr. L. A. Conner.

The author's references will appear in his reprints.

General Theory of the Neuroses

By ALBERT POLON, M.D.
New York.

PART III.

CLASSIFICATION OF THE NEUROSES.

One in quest of a classification of the neuroses, approaching psychoanalysis in the hope of finding therein a settled system of grouping of types of mental disease, is bound to meet with disappointment. Psychoanalysis does not work with rigid formulation. Its concepts are not sharply delimited; in this regard it shares the characteristics of every new and growing science. Its main work thus far was concerned with the description of empirical data. Of course this description was carried on in the light of certain abstract ideas, which were also applied for the purpose of correlating these data. Unavoidably these ideas must be in a certain measure ill defined in order to facilitate their adaptability to the ever growing material they deal with.

One of the main prerequisites of the psychoanalytical attitude of mind, is a forbearance toward the unsettled condition of the material it deals with. In but few things has the last word been said. There must also be preparedness for a change of concepts or of formulations in the light of accumulating experience. "Progress of knowledge does not tolerate rigidity of definition" (Freud). This consideration applies with especial emphasis to the matter of classification.

Before all, the psychoanalytical criteria of what does and does not constitute a sound mental state are not sharply drawn. Generally speaking the concept of a normal adult may be expressed in terms of an expedient distribution of the libido. In such an individual we would find a balance of the libidinous charge apportioned between the various phases of the personality. First, his ego would correspond to the cultural level of his social environment, by having created in it the prevalent standards of morality, shame, disgust, conscience, sense of reality, judgment, logic, etc. Secondly, he would have a certain number of sublimated libido activities, such as love and interest in work, active association with his kind, an impulsion for service, love of nature, artistic, scientific, and religious pursuits, devotion to family group, or national interests. Thirdly, a certain amount of his libido must find its consummation in a heterosexual relationship with a person consistent with the level of his own ego and his selfesteem. In addition this normal individual would have no points of fixation in his development—that is, he should show no tendency to regression. Also he would not be marred by a pronounced defect of his organic structures, which could handicap his adjustment. His libido would then be expediently distributed; the gratification attained would not tend to call forth conflicts.

Clearly the pivotal point upon which this configuration rests is that it is acceptable to society, since it represents a successful repression of all those impulsive tendencies which threaten the very existence of culture. Yet an outstanding feature of this criterion of the normal is that it admits of a considerable fluctuation of the limits it sets up, and hence tolerates a large number of gradations of its standards. As for example, excessive religiosity, inordinate idealism, superstitions, are not necessarily regarded as marking an abnormal individual. Because of these gradations there is an imperceptible fusing, or shading off of the mentally sound into the mentally ill. Psychoanalytically, one is concerned but little with the qualitative differences between health and disease. It is the quantitative factor that is stressed. Freud's phrase: *"Ein jeder mensch hat ein wenig neurose"* (Every person is somewhat neurotic) expresses this point of view.

The neurotic differs from the normal essentially in that he has not successfully repressed his unconscious, which under the disguise of symptoms attains a gratification that could not have been otherwise granted, either by his ego or by his social setting. It is true that the neurosis eventually creates difficulties and handicaps for the subject; but its earmark is, that the unconscious craving causing it is sufficiently camouflaged to permit its manifestation without evoking social disapproval, or its equivalent, the disapproval of the socialized portion of the personality of the patient.

Society forgives and tolerates anything which bears the imprint of effort to hold the unconscious in check. Upon this ground the neurotic lays claim to and is accorded social sympathy. However, this sympathetic attitude is prone to change rapidly, as soon as the masking becomes transparent. From this point of view one may say that in the neurosis the problem of social conflict plays a rather unimportant part; in fact, the neurosis has been brought about in order to avoid it. This elimination of conflict by means of the camouflage of the unconscious is just as effective in the neurotic himself. He found a compromise formation between his censoring functions and his tabooed cravings, in symptoms which disguise for him their nature. The neurotic would be in need of this mechanism of concealing even if he lived outside the social pale.

Whereas the elimination of conflict is the primary work of the neurosis, in psychoses the situation is entirely different. There the subject is spared the internal conflict by the removal of the censorship, but the laying bare of his unconscious places him in a position of being a threat, and intolerable to society. The main characteristics of the psychotic, his being a social burden and a danger, his incapacity for *en rapport,* his diminished relation to reality, and his lack of insight, all these are the expression of a person who uncovers his unconscious to society.

Thus, the normal, neurotic, and psychotic are concepts based principally upon the rôle that the unconscious plays. This rôle, its scope and intensity, depends upon the quantity of the libido accorded to it from the foreconscious and consciousness. The more libido is detached from the latter two, the more of it accrues to the unconscious. Listening to the rambling of a psychotic is to pay a visit to the unconscious. In the neurotic one sees it disguised behind the symptoms. In the normal one sees it made powerless through sublimation and reaction formation.

It would perhaps stand repetition, that these categories are elastic and fluid, gradually shading off one into the other. It is because of this, that neurotic and psychotic diseases do not lend themselves to a grouping of sharply delimited entities; and this apart from the fact which Freud has emphasized, that in mental disease one has to reckon with the disease process itself, the reparative phenomena, and remnants and rests of the formerly normal state. For this and the preceding reason a rigid classification of clearly defined types of mental abnormality is hardly to be expected in the present state of the material. Nevertheless, psychoanalysis is guided by two main principles of classification; one determined by the magnitude of the precipitated trauma and the other by the tendency to regression.

In our discussion of the etiological factors of the neuroses, we have stressed the importance of the process of regression to points of fixation of the libido. In doing so room was left for a misunderstanding regarding the rôle of the accidental or precipitating factor at the time of the outbreak of the disease. We have stated that the last event which calls forth the neurosis is merely the last straw that breaks the camel's back. This is true in such diseases as hysteria, compulsion neuroses, and schizophrenic psychoses, which constitute the bulk of the psychiatric problem. But there are also clinical entities in which the regression plays only a subordinate part, and in which the accidental trauma overwhelmingly represents the overload under which the balanced distribution of the libido becomes disorganized. The patient, otherwise well adjusted, may be confronted by an actual situation which, proving to be beyond the limit of the elasticity of his organization, will undergo a change varying from a slight deviation of his makeup to a profound psychotic alteration. A neurosis then can arise under the overweight of an actual contemporaneous experience. Such a neurosis is termed true. Its distinctive mark is negatively the subordinate part that regression plays in it. Its pronounced feature positively is the fact that the pathogenic event induces actual pathological changes in the organs, such as congestion, stasis, tension, interfering with normal functioning. Besides the impaired efficiency due to this interference, there is also associated an at first unmotivated anxiety, which arises whenever an organism finds that its libido is not in a condition of adequate distribution.

In the light of this criterion of the primary somatic change, the three diseases, neurasthenia, anxiety neuroses, and hypochondrias have been designated by Freud true neuroses.

Neurasthenia has for a long time been a gigantic waste basket from which by degrees clinical entities, such as hysteria, compulsion neurosis, and anxiety neuroses have been differentiated. Under its vague meaning were embraced all sorts of organic conditions, which later were found to be commencing stages of organic ailments, such as general paresis, neoplasm, arteriosclerosis, endocrinopathies, etc.

Psychoanalytically, neurasthenia has a restricted meaning in terms of its specific etiology, namely masturbation. The stand that psychoanalysis takes regarding the etiological significance of masturbation is midway between the extremes of the prevailing views. These extremes, as you know, are to the effect that masturbation is an extremely noxious agent, even when practised moderately; the other, that it is in itself harmless, and is to be regarded as a symptom rather than as a cause. Guided by observation, psychoanalysis regards masturbation, when practised excessively, as the cause of neurasthenia, that enigmatic entity which is characterized by fatigability, mental and physical, dyspepsia, spinal pressure feeling, frequently by low blood pressure, etc.

Freud's conception of the normal sex function illuminates the genesis of neurasthenic symptoms. In the sexually ripe male organism probably there is being produced, continuously, the somatic sex excitation which becomes the stimulus of psychic life. This somatic excitation, the result of visceral function, is able to reach the cortex only after it passed over a certain threshold maintained by an insulation of the conducting pathways. Having reached the psyche, various ideational groups are energized by the libido, which are set in motion for the removal of the created tension. A good deal of this energy is utilized for the intrapsychic organization, such as the ego, a large amount of it is directed to sublimated sex activities, but a certain quantity of this energy can be unloaded only by means of a specific adequate action. This for the male consists in a complicated spinal reflex act, preceded by an efficient psychic preparedness. Masturbation is a shortcircuiting of this process. With the slightest stimulation the libido is driven into a channel of outlet which does not aim at a change of the outer world, so characteristic of the higher organisms. The outlet in masturbation is found in the body itself. Freud termed reactions of this sort, which transpire only within the organism, as autoplastic, in contradistinction to the alloplastic, that is, those which express themselves in attempts to change the environment. This shortcircuiting of the libido in masturbation is followed by a diminution of the tone of the entire personality; mentally and physically there is a reduction of vigor, initiative and capacity for exertion. An actual defect of organic function underlies neurasthenia, hence it is termed a true neuroses.

The damage resulting from this practice is in two directions. On the one hand there is a lowering of efficiency, and on the other it often engenders a conflict in the subject. Many masturbators seriously injure their psychosexual apparatus so that they are disabled to carry on a normal sexual life—they suffer from impotence, ejaculatio precox, etc. The conflict and the inefficiency may in themselves give rise to another neurosis, such as hysteria or compulsion. That is why neurasthenia rarely occurs in its pure state. There is always an admixture of signs belonging to other neuroses. Clearly the most important side of the therapeutic approach is on the side of prophylaxis and of suspension of the practice of masturbation.

The second clinical entity classified as a true neurosis, and yet distinct from neurasthenia on the one hand, and from hysteria on the other, is anxiety neurosis. Its chief features are hyperesthesia of the special sense organ, general irritability, unmotivated anxiety—a tendency to anticipate the most untoward outcome of the most innocent occurrences, and spells of sudden anguish without any special ideational content preceding it. As a rule the spell is associated with a feeling of an impending calamity, death, dreadful disease, or insanity. With this anxiety there are usually associated functional disturbances of respiration, circulation, vasomotor and glandular innervation. Now one, now the other may be emphasized. Frequently the whole of the neurosis may express itself in a rudimentary form, in which the only pathological manifestation is that of one or another bodily function, such as palpitation, digestive disturbances, excessive sweating, diarrhea, vertigo, vasomotor edemas, and spells of paresthesia. Then again the whole anxiety may express itself in pavor nocturnus attacks, in the adult. An important clinical form of anxiety is that associated with spells of vertigo, loss of equilibrium, or even fainting. The anxious anticipation may lead to formation of phobias, such as those pertaining to animals, thunder, darkness, etc., or those that pertain to locomotion termed agoraphobia. Many of these symptoms may become chronic, and be the only rudimentary indication of the anxiety.

These symptoms have been observed by Freud in relation to a special etiology. In females it is found in virgin adolescents, in the newlywed woman, who is sexually anesthetic, in married women whose husbands suffer from ejaculatio precox, are impotent, or practice coitus interruptus, in the abstaining widows, and in women during the climacteric rise of the sexual appetite. In the males anxiety neurosis is observed in total abstinents, or in the engaged man who frustrates his excitement, or in the married man who practices coitus interruptus, or in men of advanced age whose potency did not keep pace with their libido. Finally, both male and female neurasthenics, upon giving up the practice of masturbation, manifest anxiety. They have become especially unable to endure abstinence.

The whole syndrome of anxiety neurosis, the mental phase of anxiety as well as the disturbance in the bodily functions, is engendered by the damming of the libido. This conception is confirmed by the fact that the analysis of this clinical entity does not reveal any other basis, and also by the fact that correction of the errors of sexual life enumerated above leads to a rapid vanishing of the symptoms.

This neurosis offers the opportunity for the understanding of neurotic anxiety in general. Anxiety is clearly related to fear. Fear, anxiety, and fright are terms for types of affective reaction, frequently used synonymously, but they have been assigned a definite connotation in psychoanalytical literature. Fear is used to designate an affect called forth by a threat coming from the outside world. One fears a bear, a dangerous crossing, or an impending calamity. Anxiety is the preparedness of the organism to meet the threatening danger. It is an anticipation of it. As such it has a definite biological function. Fright is the being overwhelmed by fear without the preparedness of anxiety. Such is the meaning of anxiety when applied to situations which arise in reality, and as such are to be classed as normal.

But anxiety can also arise under conditions where the anticipated danger is not without, but within the organism. An intense tabooed craving, not approved by the ego, is reacted to as if it were a source of danger. The anxiety is a preparedness to meet the obtruding threat. At first this anxiety is undifferentiated and unmotivated. In such a condition it is expressive of the free floating state of the libido. Later on it may attach itself to special ideational systems, and losing its free floating character becomes, what is clinically termed phobia.

The mechanism, by means of which the free floating anxiety is harnessed on to things of the outer world, is termed projection. As long as the subject is experiencing the threat from within, he cannot make use of his psychomotor apparatus for purposes of flight or protection. There is no way of relieving the state of tension created thereby. But when he projects his anxiety outward, that is, when he begins to be anxious about snakes, thunders, calamity of business, etc., he accords himself a relief by the exercising of his psychomotorial functions. All phobias thus represent a reparative process, tending to anchor the free floating libido.

These considerations of anxiety help to understand why it occurs so often in mental disturbances, since in every mental disturbance there is always some unattached libido. Secondly, in this light the relation of anxiety neurosis to anxiety hysteria becomes comprehensible.

What is of interest here is the fact that anxiety can be induced by purely organic conditions. This is surely the case in anxiety neurosis which comes and goes with errors in sexual life, such as those mentioned above. The regular effective therapeutic procedure of this disease is the discontinuance of the subversive practices, such as complete abstinence, coitus interruptus, frustration of sex appetite, etc. The genesis, as well as the mode of its correction, via the soma, places anxiety neurosis among the true neuroses.

The third disease designated as a true neuroses is hypochondria. Hypochondria resembles the feelings and mental state accompanying organic afflictions. Every sick man detaches his interest and his object libido from the outer world and places it immediately upon himself during his ailment. The foremost point of interest to him would now be the diseased part of his body; and it is well that he does so, for otherwise the restitution process would be delayed. This is equivalent to saying that a libido transference is necessary even in cases of organic disease.

The hypochondriac does exactly the same thing. His mind is centred upon one or more organs. The difference, however, from the condition of the organically ill, is that in hypochondria there is no demonstrable gross pathological change; and yet there can be but little doubt that the basis of his paresthesias, dysesthesias, etc., are circulatory changes. A consistent feature of the hypochondriac is the fact that his libido is devoted but little to objects. Its bulk is in the body of the patient, inducing congestive states. The congestion and tension thus induced stand in relation to the erogenic qualities of the various organs. In a large measure the hypochondriac, having abandoned the objects for his libido, and with that normal psychosexual activity, genitalizes other organs than those suitable for the reproductive function. The organically sick man gives up his autoerotism, in connection with the diseased organ as soon as he recovers, because a good deal of his libido is objective. The hypochondriac, not able to maintain his libido in the outer world, finds himself compelled to reckon with its effects within his own body.

The anxiety associated with the sensory symptoms in hypochondria is the manifestation of the free floating libido not anchored by the organs. In proportion as the hypochondriacal anxiety increases and calls for a psychic elaboration, to the fore begins to come the picture of schizophrenic psychoses, or as Freud called it, paraphrenia. Hypochondria bears about the same relation to narcissistic psychoses as the other two true neuroses bear to hysteria and compulsion neuroses.

This group of true neuroses, apart from the pragmatic value of their being thus classified, is of great theoretical interest. They are instances of bodily changes, induced by abnormal psychosexual function.

We have perhaps devoted an undue amount of time to the consideration of the true neuroses, since the topic of this presentation is the subject of classification. But, since in the previous article, on the genesis of neuroses, the regression element has been stressed, perhaps to such a degree as to obscure the significance of the true neuroses, it was deemed advisable to dwell upon the true neuroses somewhat more extensively than our theme would ordinarily call for. With this digression into the first group of neuroses, called the true, we shall proceed with the attempt to classify the rest of the neuroses, constituting the bulk of the clinical pictures of mental disease.

A neurosis which is not a true neurosis, in the sense in which we have indicated above, is a regression neurosis. In the light of previous remarks, a regression is a reversion to a fixation point of development of the libido. In this process of regression, one has to distinguish, first, the depth of the reversion, and second, the quantity of the libido reverted.

You will recall that the developmental course of psychosexuality, even in the normal, is marked by special stages. These are: First, the autoerotic stage of the first year of life in which the mouth region plays a predominant rôle as a source of gratification. This stage is also termed autoerotism. The mental processes expressive of the dominating impulses of this period are termed narcisic. The name, first pregenital stage, is also applied to this epoch.

The second stage of development of the libido, lying anywhere between the second and the fourth year of life, is marked by a still persisting tendency of partial impulses to manifest themselves autonomously. These libidinous strivings are not homogeneous as regards the content of love and hate. In other words, they are ambivalent. The body area acting as the source of excitation is foremostly the rectal and urethral openings. The sadistic impulse plays a conspicuous rôle.

The third or last stage of infantile sexuality, termed the stage of genital supremacy, is characterized by the surrendering of the excitation quality on the part of all erogenic zones to the genital area. This condensation of the erogenic zones into a unity, is paralleled by a well marked tendency to attach one's love life overwhelmingly to one person, usually one of the parents. This stage is also called the stage of object libido, but the objective tendencies of the libido also mark the second stage.

The development of the libido thus proceeds in two distinct directions. One direction is towards the formation of a hierarchy of the partial sex impulses, finding its expression in the adult sex impulses; and the other direction is of a gradual relinquishing of one's own body as an object of the libido and the application of the love striving to an outside object or person.

It should also be borne in mind that these stages are not sharply delimited; they override each other. Characteristics of an earlier period are found in a later one, and vice versa.

A regression taking place to any of these stages emerges in a mental configuration which bears the imprint of the depth to which it descends. It is also clear that in no case does the total amount of the libido regress. Some of it may remain attached in a normal way. And then again not all of the regressed libido remains at the point of fixation. Restitution phenomena take place. The regressed libido may make an attempt to return to reality. These attempts, of course, will be stamped with qualities of the fixation points from which they issue. They will be compromise formations. Thus, the formation of the neuroses depends upon the regressed libido and upon the restitution efforts.

FIRST GROUP OF REGRESSION NEUROSES.

The first group of the regression neuroses are the psychoneuroses, also termed transference neuroses. In these, the regression takes place to the second and third stages of the infantile development. Accordingly, the unconscious fantasies of these ailments are bound up with a person who played an important libidinous rôle during the childhood of the subject. This fantastic devotion to a person in the past is rather elastic and is capable of being transferred to some person in the reality of adult life. Because of this quality, so helpful in psychotherapy, these neuroses are termed transference neuroses. The designation psychoneuroses is derivable from the fact that they are psychogenic in origin.

In spite of the fact that the third stage of libido development is characterized by the genital supremacy and by the objective character of the love striving, the child at that age is not capable of carrying on a normal psychosexual activity. Under inordinate stimulation various parts of the body participate by way of substitution. The hysteric returning to that stage manifests the tendency to genitalize various sensory motorial and secretory mechanisms for the obtaining of the unconscious gratification. The hysterical bodily symptom is a symbolic presentation of the heightened erotic rôle which a particular organ played at the time of infantile activity. As such, the symptom is expressive, on the one hand of regression, and on the other, of restitution efforts, embraced under repression. The quality of the hysteric to genitalize various parts of his body has been designated by Freud as conversion. It constitutes the distinctive feature of hysteria.

However, not always does the entire quantity of the regressed libido become localized in the conversion phenomenon. A good deal of it may remain unattached, and as such, would manifest itself as a free floating anxiety. The unendurable state of unmotivated, or as it has been called, free floating anxiety, calls for its anchoring. This is accomplished by a displacing of anxiety to some external object, giving rise to phobias. Conversion hysteria, as a rule, is mixed with anxiety symptoms, and the syndrome is termed anxiety hysteria.

In compulsion neuroses the regression takes place to an earlier stage, the second stage of pregenital organization. The object choice is present. But there is no supremacy of the genital zones, nor is there a condensation of the partial impulses, nor is there a heterosexual differentiation of the object. The rectum and urethral openings play an important rôle. The ambivalence of feeling is prominent. The sadistic strivings have not yet receded. The object is often homosexual. Obstinacy, lack of readiness to surrender anything of one's self, and preoccupation with excreta at that period, reverberate in the doubts; ambivalence, pedantry, and stinginess of the compulsive, whose mental picture is expressive of sadism and anal erotism. This process in the compulsive neurotic transpires chiefly on the level of psychic elaboration. Conversion symptoms generally are absent.

Although the compulsion neuroses represents a regression to an earlier libido position than that of hysteria, the two diseases have one feature in common. The receded libido is objective, and therefore can shift its position from the fantasy on to the analyst, and from him on to the problem of normal adjustment.

Conversion hysteria, anxiety hysteria, and compulsion neurosis make up the first group of the regression neuroses.

SECOND GROUP OF REGRESSION NEUROSES.

The next group of syndromes of regression, termed narcissistic, are characterized by a reversion of the libido to positions of the first and second pregenital stages, namely, autoerotism, narcissism, and anal erotism. The restitution attempts of this descent are made largely by means of the mechanism of identification to projection, clearly representing the infantile mark of the attempts to return to reality. Due to the fact that in those early stages there was a marked disorganization of the impulses, and that the attempts at reconstruction would therefore issue from various fixation points, the emerging mental pictures would be greatly varied.

Prominent among these syndromes are the persecution and egomania psychoses. Here the libido descends to narcissism, homosexuality and sadism. Against these cravings the ego defends itself mainly by ascribing to the outer world the impulses which rage within the subject. Hence, the persecution mania. A certain part of the regressed libido in the attempt at restitution is taken up into the ego with the resulting egomania. The receded libido loses its objective character.

The depression psychoses are a recession to the first and second pregenital stages. The restitution efforts are carried mainly by the mechanisms of identification. After the disappointment in some object choice of reality, the patient introjects the object or person into his ego. The higher levels of the ego, termed ideal ego, rage and storm and condemn the introjected portion of the ego. The self-depreciation and selfdenunciation of the depressive is the evaluation by the ideal ego of that portion of his ego which he has unconsciously identified with some disappointing person. The suicidal tendency is an attempt to kill the one whom he loved, in other words, his love is expressed now in a sadistic form. Revenge is the keynote of the suicidal mania of the depressive.

A complete emancipation from the tyranny of the criticizing and condemning ideal ego manifests itself as the manic phase of the manic depressive psychoses.

Both in paranoia, as well as in depressive psychoses, the regression leads to a reoccupation of positions of oral and anal erotism with sadistic strivings. That much they have in common. The difference between them is that the paranoic seeks relief from the overloading of the infantile position by projection. He storms against the outer world. The depressive, on the other hand, attempts to reduce his state of tension by means of injury to his own person. The taking on of the regressed libido by the ideal ego, resulting in egomania, as well as the seeking of relief from the thus resulting hypertrophied ego by means of projection (world catastrophe) are the chief restitution phenomena of paranoia. The restitution phenomena in the paranoia express themselves in the egomania resulting from the taking on of the regressed libido by the ego. The attempts to change the world (world catastrophe), is an effort to relieve the tension of the hypertrophic ego by means of the narcissistic mechanism of projection.

The generic group of schizophrenic psychoses embrace various forms of regression to various points of fixation in the stage of autoerotism. Even a superficial consideration of their characters would be precluded by the limitations of this paper. The states of acute confusional and of acute catatonic excitement are to be regarded as regression phenomena, in which the restitution process is at its minimum.

In all these syndromes Freud distinguishes, first, a certain residual amount of normalcy; second, the regressive disease processes *per se,* consisting of the detachment of the libido from normal objects and its occupation of infantile positions; third, the restitution efforts which are tinged by the particular point of regression. In this sense the neuroses and the neuropsychoses are compounds of various constellations of the libido distribution, not unlike a mineral composed of various ores. A predominating feature would be the main characteristic; but by describing it alone, one would not convey the idea of the mineral as a whole. It is for this reason that no psychiatric case fits the frame of any syndrome. There is always something more than the syndrome embraces. That something more in the case, which makes it vary from the textbook description, is to be found in the dynamic phase of the ailment, namely, in the restitution efforts. A syndrome is at best a static abstraction. The mental disease is a dynamic process. Its dynamism is derivable from the impulses for reconstruction; from the attempts to return to reality. A psychoanalytical classification, therefore, does not aim at the delineation of morphological entities, but rather seeks to indicate the direction in which the libido impulses operate, and the developmental levels from which they issue. It is with this reservation that these remarks on classification have been made.

Influence of Glucose on Phagocytosis in Vitro*

By GEORGE RUBIN, M. D.
And MORRIS L. ARKIN, M. D.
Chicago, Ill.

The marked susceptibility of diabetics to various infections has been noted by many observers. No definite explanation has, so far, been made. Undoubtedly many factors operate in affecting the natural resisting power of the individual with a hyperglycemia. We undertook to study one phase of the mechanism of immunity, namely, the influence of glucose, of lactose and levulose, and of acetone on phagocytosis in the test tube.

TECHNIC.

Solutions of glucose, lactose and levulose, in various strengths, were introduced into suspensions of dog's blood. To these and to control tubes emulsions of bacteria were added and the effects on phagocytosis were noted. Chemically pure glucose, lactose and levulose were used to make up stock solutions, ten per cent. of each. The diluent was normal salt solution. After the ten per cent. stock solution was made up it was sterilized. Dog's blood was defibrinated immediately after drawing. Glucose, lactose and levulose solutions of 0.01 per cent. increasing to five per cent. were made up in different tubes of blood, each containing one c. c. The sugar solutions were made up so that the proper amount was contained in one c. c.

The bacteria used were twenty-four hour cultures of streptococcus, staphylococcus aureus, and pneumococcus Type I grown on human blood agar slants. The bacteria were washed off with normal saline. To one c. c. of blood was added the proper amount of sugar in normal saline to make up two c. c. The control consisted of one c. c. of blood plus one c. c. of normal saline. The tubes were incubated for half an hour at 37° C. to allow the sugar to penetrate into the cells. At the end of this period one c. c. of the bacterial emulsion was added to each tube and to the control tube. The tubes were then thoroughly shaken to mix the blood cells with the bacteria and reincubated for half an hour. Smears of the blood were made and stained with Romanowsky, Wright or Skelton's stains.

The bacteria in one hundred cells of each of the preparations were counted and recorded. We found absolutely no difference in the average number of englobed bacteria to the leucocyte in the sugar treated or control blood. These experiments were repeated several times with the same results.

It was then thought that perhaps the acetone, the principle of the ketone body, a byproduct of hyperglycemia, had some detrimental influence on the phagocytes. So we undertook a few series of experiments with acetone dilutions of 0.1 per cent. to 1.0 per cent. Acetone in the concentrations used also had no effect on phagocytosis in vitro.

One series of experiments was made with human diabetic blood. A man, thirty-five years of age, who had been under the observation of one of us (Arkin) had a blood sugar of 0.22 per cent. The same technic was employed as in the previous experiments. The patient was then made to fast twenty-four hours, after which his blood sugar was only 0.10 per cent. The phagocytic function did not vary in the specimen with 0.22 per cent. blood sugar and that with 0.10 per cent.

The figures of sugar concentrations of dog's blood in all the specimens were exclusive of the normal blood sugar content. The dog employed in our tests had 0.14 per cent. blood sugar.

CONCLUSIONS.

1. Glucose in the blood, even in the high concentrations, has no influence on the phagocytic function of the leucocytes and we have reason to believe that it has no detrimental effect on the cells of other tissues.

2. The susceptibility of diabetics to infection is probably due to, a, a more favorable medium for bacterial growth, and b, the increased viscosity of the blood resulting in sluggish capillary circulation with consequent stasis and infection.

Experiences with Insulin in the Treatment of Severe Cases of Diabetic Acidosis with Impending Coma*

By JOSEPH S. DIAMOND, M.D.,
New York.

The unique and spectacular manner with which a severe case of diabetes responds to insulin therapy is of more than ordinary interest. In two of the cases herein reported the patients were *in extremis*. One, a child in whom the grave symptoms developed acutely, one might say within one week, presented terminal stages of acidosis with a picture of imminent dissolution. The second was a diabetic of three years' duration, with a loss of fifty-six pounds in weight and with symptoms of impending coma, such as dimness of vision, extreme weakness, loss of memory, inability to recognize relatives and friends, with a blood sugar of 560 mgs. and a carbon dioxide combining power of 32, large amounts of acetone and diacetic acid and betaoxybutyric acid. Under insulin therapy the response was immediate. In one of the cases the danger was overcome within less than ten hours.

Case I.—I. A., a boy of nine and a half years, was referred to me by Dr. J. Weiss, on April 6th, and it was due to his prompt recognition of the nature of the disease that the patient's life was saved. The history elicited was that some time in February of this year the boy had an attack of influenza, after which he apparently made a good recovery, the only symptom pointing to the development of diabetes being an increase in the frequency of micturition. The boy would void once at night and would ask the teacher once or twice to leave the room during school hours which he had never been in the habit of doing previously. The condition passed unnoticed by the family until the end of March, just a week prior to the development of acute symptoms of acidosis. At that time the patient had lost some weight and was growing weaker. A physician was consulted who made a physical examination of the patient, omitting the urinary examination. The parents were told that the boy was undernourished but otherwise in good physical condition, and did not suffer from any organic disease. The physician recommended forced feeding, particularly starches, fats and sweets. This treatment was carried out for a week, the patient becoming weaker and feebler every day, and lost weight steadily, from sixty-four pounds to forty-eight.

Two days before I saw him he became bedridden from sheer muscular asthenia. When I saw him his pulse was 150, his skin was dry, icy cold and wrinkled, his face had an aged appearance. His tongue was dry and leathery, his eyes were half closed, he had a marked acetone breath, he was so weak that he was unable to turn from side to side or move any extremity. When spoken to he attempted to mumble faintly in an inaudible and unintelligible manner. His urine was full of acetone and diacetic acid and contained 6 per cent. sugar. Carbon dioxide combining power of blood was 28 c. c. per 100 c. c. with blood sugar of 600 mgs.

At 6 p. m. of the same day, the administration of iletin was begun, the initial dose being ten units. There was no change within three hours, we therefore increased the dose to fifteen units which was repeated every three hours until the following morning. The patient was kept warm with artificial heat and was given nothing with the exception of water, tea and brandy in small doses, as much as the patient was able to swallow, as during the first hours it was hardly possible for him to take anything by mouth. Within ten hours after the first dose of iletin (or after a total of seventy units were given) the patient's pulse dropped to 90 and a general improvement, particularly in muscular strength, was noted. The extremities became warm, face flushed and his tongue moist. Later in the day the pulse dropped to 80, the acetone, diacetic acid and sugar steadily decreased. In two days they had entirely disappeared. His improvement was prompt and steady. The iletin was now cut down to ten units three times per day. The patient was placed on a substantial mixed diet, more carbohydrates were gradually added to the fats and proteins, so that within several days the patient consumed fifty grams of carbohydrates. On the second day the patient sat up, but was kept in bed for five days. At the end of that time he had gained eight pounds. Since then, he continues to be sugar free, is in excellent health, participates in all games with his friends and on May 6th, exactly one month after the onset of the treatment, he weighed sixty-six pounds, that is, a gain of eighteen pounds in a month's time.

The further observations in this case brought out some interesting developments. After a month's insulin treatment it became apparent that he required less insulin in order to keep sugar free. Whereas before, during the entire month, he consumed thirty units daily on a diet of fifty grams carbohydrates, seventy-five grams protein, one hundred grams fat, we now found that we could diminish the insulin daily so that within two weeks he consumed but five units daily, even though his carbohydrates were increased to seventy-five grams. Recently the insulin was withdrawn for one week and the carbohydrates diminished to fifty grams. The patient still continues to be sugar free. I believe that here we have a case that presents almost a complete restoration of the pancreatic function.

Case II.—Mrs. M. L., aged thirty-four. Married twelve years, sterile. The family history was negative; father, mother, four sisters, one brother alive and well. The patient had typhoid fever at the age of eighteen from which she made a good recovery.

During the summer of 1919 she was in good health and spent her vacation in the mountains, she gained sixteen pounds in six weeks, weighing then 146 pounds. When she returned in September she began to experience weakness and a constant tired and sleepy feeling. The patient had polydypsia, polyphagia and polyuria, and in spite of these pronounced symptoms no diagnosis was made until the end of January, 1920, when the urine was finally examined and 2.5 per cent. sugar was discovered. Under strict regime the patient lost twenty-two pounds within three months, never fully clearing her urine of sugar. After that she was put on a more liberal diet of oatmeal and she gained five pounds in one week. But soon after her urinary sugar rose from 6 to 7 per cent. She again lost weight and felt extremely weak, when she again returned under strict regime. Since then the patient never rallied. There was a gradual decline in weight and strength. Her urinary sugar varied from 3.5 per cent. to 6.5 per cent. During the year of 1922 an ever increasing acetotonuria developed and later diacetic acid. The patient grew so feeble that she was mostly bedridden, unable to perform any of the slightest household duties and did not have the strength to "turn the faucet." During December, 1922, she began to complain of pain and numbness in the right lower extremity from the knee downwards, the numbness being confined particularly to the outer three toes.

---

*Read before the Eastern Medical Society, May 11, 1923.

On January 21, 1923, the patient was brought to me. I found her extremely feeble, her weight was ninety pounds. The casual specimen that morning contained 6.3 per cent. sugar with large amounts of acetone and diacetic acid. Her blood sugar was 560 mgs. The carbon dioxide combining power was 32. The pulsations in the dorsalis pedis and internal tibial in the right foot were scarcely perceptible, in the left they were normal.

Before the administration of iletin an attempt was made with the Allen treatment of starvation, to see what could be accomplished and whether it would be possible to improve her acidosis condition and raise her sugar tolerance, and although this treatment was carried out with scrutinized care, the condition grew worse from day to day, the acetone diacetic acid and betaoxybutyric acid continued unabated, the carbon dioxide combining power remaining unchanged. The patient steadily declined.

On February 1st, we began to administer ten units of iletin subcutaneously three times daily, half hour before meals, the diet remaining unchanged. After the first day following the administration of thirty units of iletin the acidosis completely disappeared and the urinary sugar came down to 2 per cent. On the second day the urinary sugar likewise disappeared and the blood sugar came down to 180 mgs. The patient was then put on a fairly liberal diet including 100 grams of bread, half a grape fruit, 500 grams of vegetables, six eggs, 75 grams chicken, 500 c. c. sweet cream, thirty grams fish, thirty grams butter. The total being 100 grams carbohydrate, seventy-five grams protein, 150 to 175 grams fat, a total of over 2,000 calories. The iletin was continued daily increasing the dose occasionally to twelve and fifteen units a dose. The general wellbeing of the patient promptly improved, the asthenia disappeared, mentality became clear, the pain in the leg and the sensation of numbness disappeared. The patient was allowed out of bed for a few hours every day. Her weight steadily increased at the rate of half pound a day so that within five weeks she regained twenty pounds. At the present time, after three months of iletin administration with an occasional interruption, the patient weighs 120 pounds, showing a gain of thirty pounds.

We found on close study that if we wanted to keep the patient sugar free and with a blood sugar approaching normal it would be necessary to give her from eighteen to twenty units of iletin three times a day instead of ten units as were administered. We could thus ascertain in mathematical figures the exact amount of carbohydrate combustion to the unit of iletin. In order to follow this up more closely and to gauge the combustion influence of iletin to the unit, I conducted the following tests:

On March 1st, the iletin was discontinued for twenty-four hours, and the total quantity of urine collected for the same day, the diet remaining unchanged. The patient voided 2,000 c. c. of urine containing 7 per cent. sugar totaling 140 grams of sugar which was practically equivalent to the total intake of 150 grams of carbohydrate, fifty grams being derived from the protein, thus showing that the sugar tolerance of the patient was zero. This experiment was repeated the following week and the findings were identically the same, the patient eliminating 6 per cent. sugar in 2,500 c. c. or 150 grams of carbohydrate.

During these days when the patient received thirty units of iletin per day she lost from seventy to seventy-five grams of sugar in the urine from a total of 150 grams of carbohydrate partaken, thirty units of iletin had caused the combustion of half the carbohydrate taken in, that is seventy-five grams, the other seventy to seventy-five grams being eliminated in the twenty-four hour specimen. I then gradually and cautiously increased the iletin until on March 8th we doubled the amount of iletin and the patient became entirely sugar free, that is the entire quantity of 150 grams was completely metabolized by sixty units of iletin a day. From this we could deduce that one unit of iletin causes the combustion of two and a half grams of carbohydrate.

I find it best however, to keep this patient on a much lower threshold in order to avoid any complications that might arise from an overdose which might induce the now well recognized symptoms of hypoglycemia, such as nausea, vomiting, syncope and convulsions.

As to the future of this patient with a carbohydrate tolerance of zero it is difficult to conjecture at the present time. I will continue the insulin administration until her weight increases another ten pounds and then discontinue it attempting under dietetic regime to bring up slowly her sugar tolerance.

CASE III.—P. S., aged thirty-two, referred by Dr. J. Fuchs. An ambulatory patient who illustrated a severe type of diabetes with a minus carbohydrate tolerance who had reached a stage where in spite of the low intake of carbohydrate he failed to respond to the older dietetic and fasting regime. His diabetes was of less than a year's duration. Careful treatment produced now and then a temporary standstill of the disease, the condition soon however became beyond control, requiring fasting and other methods. At examination he eliminated large quantities of acetone and diacetic acid, his blood sugar was 360 mgs. and his carbon dioxide combining power was 46.

He presented all the concomitant symptoms of the disease such as marked asthenia, polyphagsia, polyuria, polydypsia, etc.

One week's treatment under insulin therapy convinced me of the severity of his case. With a diet of fifty grams of carbohydrate, seventy-five grams of protein and 120 grams of fat which would give him but 1,580 calories (weight 113 lbs.) he would require over fifty units of insulin a day to keep him sugar free. As he received but forty units a day he still lost between sixteen to twenty grams of sugar in the urine every twenty-four hours. Nevertheless, he gained eight pounds during the first week and I shall wait for further developments in the progress of his case.

Case IV.— M.F., aged forty-nine, hard working man with a history of diabetes of many years' duration. Of late he had lost twenty pounds in weight and heavy traces of acetone and diacetic acid had developed. His case was of unusual interest. Judging from his low sugar tolerance and the development of the ketone bodies, one would classify this case among the more severe types of diabetes, requiring like the previous cases a large number of insulin units to keep him sugar free. To my surprise, however, I found that one administration of ten units of insulin caused the entire disappearance of acetone and urinary sugar within twenty-four hours. Since then I found that he could be kept sugar free with eight units of insulin and with a carbohydrate intake of fifty grams a day. Whether the insulin had a more potent effect in this case or whether the function of the pancreas becomes partly restored is a question of further study.

CONCLUSIONS.

In insulin we have a substance that prevents coma and death from diabetes but does not cure the disease. It may help to restore the carbohydrate tolerance as in Case I, where an acute pancreatic insufficiency took place. In such cases by giving a complete rest to the temporary disabled pancreas, during which time the patient's life and health are safeguarded, the function of the pancreas may be restored to normal activity. This has not been observed in the adults herein reported.

Aside from coma, insulin is indicated only in those severe cases in which the ordinary dietetic treatment fails to bring a response and in those in which ketosis begins to develop. It has no place and should not be used in the moderate diabetic patient. Here the standard dietetic treatment gives satisfactory results. When used, it promptly restores the patient to a normal standard. Unlike thyroxin, the human economy behaves differently to this isolated internal secretory substance. While in the former, the intravenous injection of one mg. of thyroxin in a case of cachexia strumipriva, will restore the metabolism to normal and will cause it to remain so for a period of two weeks, in the latter unfortunately, its influence is only temporary, the iletin is promptly utilized in influencing mobilization and metabolism of the carbohydrates. The effect is temporary. With each combustion of carbohydrate a definite unit of insulin is consumed and therefore the substance must be administered with every meal. Also, unlike the extracts of pituitary or thyroid this substance cannot be administered by mouth as the digestive enzymes cause its destruction.

In the face of all these difficulties, however, do not let us dwell too long on the pessimistic phase, but let us be reminded of the pitiful and erstwhile helpless state of these patients and ask ourselves what would have become of these patients were it not for insulin. I will quote no less an authority than Frederick M. Allen in his laconic remark, "that insulin is the greatest discovery of the present age."

110 East Sixty-fourth Street.

The Renal Glucose Threshold and Its Bearing on the Insulin Treatment of Diabetes

By G. W. McCASKEY, M.D.,
Fort Wayne, Ind.

By the renal glucose threshold is meant that concentration or percentage of sugar in the blood which will just barely cause the appearance of sugar in the urine. Its variability especially in disease is very great and even in apparent health the variations are considerable both in different individuals, and, though ordinarily to a slight extent, in the same individual at different times. Its greatest importance is its influence upon the diagnostic significance of the routine examination of the urine for sugar. It is now fully recognized that the presence of sugar in the urine does not prove the presence of diabetes mellitus, nor its absence disprove it. This rather unfortunate clinical fact is due mainly to the variable blood sugar concentration required for the renal excretion of sugar which may be 100 mgms. of sugar in 100 c.c. of blood (.1 per cent.) in one case and 300 mgms. (.3 per cent.) or even more in another. In the first case the glycosuria occurs with a perfectly normal blood concentration of sugar and really has nothing to do with diabetes mellitus, which is essentially a disturbance of sugar metabolism. In the other case the patient, as in one of the cases here reported, may have marked diabetes without glycosuria with a blood sugar as here reported of 300 mgms. (.3 per cent.).

The importance of these clinical observations is accentuated by the advent of the insulin treatment of diabetes, which has already taken its place as one of the great achievements of the present century. With either a very high or a very low renal glucose threshold the urine can no longer be trusted as a guide to this or any other scientific treatment. It offers an obstacle to both the insulin and dietetic treatment which can only be overcome by frequent blood sugar analyses. With the low threshold it is perfectly obvious that any attempt to eliminate glycosuria by dietetic restrictions might be attended with serious or even disastrous results. With a very high renal threshold the disease might march on unrecognized with progressive destruction of the pancreatic cells which furnish the insulin in the patient's normal chemistry, unless the observations are checked by repeated blood sugar analyses. The practical difficulties presented by the very high renal threshold in carrying out the insulin treatment are well illustrated in the second case here reported.

Case I.—Low renal threshold: Mrs. B., aged thirty-seven, was first seen October 17, 1919; the principal complaint was nervousness and back pain. Physical examination showed the thyroid gland slightly enlarged and palpable; heart normal in size, rhythm and sounds, except an undue accentuation of the second sound at the base; heart rate ninety. Abdominal and pelvic examination was entirely negative.

The urine constantly contained sugar ranging from 200 mgms. (.2 per cent.) to 500 mgms. (.5 per cent.). The blood sugar at this time was 110 mgms. in 100 c.c. of blood (.11 per cent.). The patient had a moderately severe grade of hyperthyroidism, the basal metabolic rate November 18, 1919, being plus 37.7 per cent. Many blood sugar and urine examinations were correlated over several months and the renal threshold was found to vary from .11 to .12 per cent. Other blood findings were cholesterol 198; N. P. N. 39 and uric acid 3.3 mgms. to 100 c.c. of blood. This patient improved under a suitable line of treatment, the hyperthyroidism gradually disappearing and the renal threshold gradually rising.

In about five months it was found that .142 per cent. of blood sugar produced a doubtful trace of sugar in the urine and later still, in about one year from time of original examination, it required 178 mgms. (.178 per cent.) sugar in blood to produce a clinically recognizable glycosuria. This is strictly within the normal range.

This case is somewhat difficult to classify. If we accept Joslin's rigid delimitations it cannot be called a case of renal diabetes because of the gradual elevation of the threshold to the normal limit within a period of about one year, and the definite influence which an increase in the carbohydrate intake was always shown to have upon the sugar output. On the other hand, it lacked the leading characteristics of true diabetes such as hyperglycemia, hyperlipemia, polyuria, etc. It seems to me that the glycosuria in this case, which stands practically alone as a carbohydrate phenomenon, is best explained simply by the lowering through some unknown mechanism of the renal glucose threshold to such a degree as to allow perfectly normal blood sugar concentrations to filter through into the urine. It does not seem likely that the hyperthyroidism had much if anything to do with the glycosuria. In this condition there is an increased mobilization of carbohydrates which could not reasonably be supposed to have any influence whatever upon the renal glucose threshold. As a matter of fact the hyperglycemia test (by the ingestion of 100 grams of glucose) did not produce as marked a hyperglycemia as has been recorded by myself (1) and others in the literature, although the glycosuria actually increased *pari passu* with the increasing carbohydrate intake and resulting hyperglycemia.

Case II.—High renal threshold: Mrs. M., aged sixty-six, health always good, except a severe attack of typhoid fever in girlhood. About six years ago while in apparently good health she had an unaccountable attack of general debility which compelled her to remain in bed several weeks. During this time sugar was once or twice found in the urine and since that time had been found occasionally. She first presented herself for examination May 7th, but a previous analysis of a twenty-four hour collection of urine had been made sixty days earlier, in my laboratory, each voidance being collected separately because of a suspicion of interstitial nephritis. This showed a normal range of gravity and not a trace of either sugar or albumin. At the time of my examination she had been partaking freely of carbohydrates, partly due to the laxity encouraged by the findings quoted above, and was excreting in the urine one quarter pound of sugar daily with a concentration of four per cent. The blood sugar at this time was 300 mgms. (.3 per cent.) and the cholesterol 542 mgms. (.542 per cent.). Other findings were as follows: blood, N. P. N., 56 mgms. (.056 per cent.); urea nitrogen, 23.9 mgms. (.023 per cent.), which equals 51.3 mgms. of urea at which time the urine urea was 900 mgms. to 100 c.c. of urine (.90 per cent.). There was a moderate acidosis as indicated by the fact that the CO_2 of the combining power of the plasma was 51.3 volumes per cent. and the pulmonary alveolar tension as determined by the Marriott colormeter method was twenty-five. These observations were not made on the same day. She was placed upon exclusive protein and fat diet and in three days her urine was sugar free and has remained so ever since. After about one week on this diet the blood sugar remained at about .27 or .28 per cent., the urine being constantly sugar free. It would seem in this case that the blood sugar in excess of about .28 per cent. freely filtered through the kidneys, maintaining the blood sugar at about the same level. A little acetone was found in the urine at times but no diacetic acid.

The cholesterol had dropped to 480 mgms.; at this time carbohydrates were added to diet and the insulin treatment begun. It is not my intention to discuss the insulin treatment at this time (which will be taken up later, probably in collaboration with others) further than to point out the difficulties which the high renal threshold presented in the scientific observation of the case. It is worth remarking here, however, that rather severe symptoms of hypoglycemia appeared when the blood sugar was forced down by the insulin to 130 mgms. (.13 per cent.), indicating the physiological adjustment to what is ordinarily regarded as a hyperglycemia. At least the symptoms of hypoglycemia appeared at what is ordinarily regarded as the normal level or really much above the normal level in the fasting state. Perhaps the blood sugar level can be gradually lowered with safety, but it is evident that it should not be done suddenly. It does not seem that there can be any doubt that the renal threshold in this case is about 280 to 300 mgms. (.28 per cent. to .30 per cent.).

The question of the renal glucose threshold deserves more clinical attention than it has received. It has been said that there is no renal glucose threshold, which is of course strictly correct if by the term is meant a constant blood sugar level as a standard of such a threshold. Joslin says (2) that we can hardly speak of a renal glucose threshold in diabetes. While this is true of diabetes it is not true of the individual diabetic patient, although I have found in common with others considerable variation of this threshold in individual cases of diabetes. There are so many factors that may influence or control this threshold, as, for instance, the crystalloid or colloid combination of the blood sugar, functional or organic renal disease, etc., that the question is a very complicated one and for the present we must be content with the determination of the threshold in each case at any given time. Fortunately, this is a simple procedure and the purpose of this paper is to emphasize its clinical importance.

On the Use of Insulin in Infantile Inanition

By ROBERT L. PITFIELD, M.D.,
Germantown, Pa.

Everyone who has used insulin in the treatment of diabetes is at once impressed with the greatly improved condition of the patient's nutrition. It is thought to be a nutritional hormone, enabling the tissues to combine with the sugar of the blood. Children suffering from athrepsia or other forms of malnutrition are of course badly nourished. Utheim found that the blood sugar of such infants was much reduced and far from being diabetic. The normal blood sugar in healthy infants appears to be about eighty, in athrepsia this may fall as low as forty-five milligrams to the 100 c. c. of blood.

Impressed with the stimulating properties of this active principle of the islands of Langerhans I tried injecting it for a period of time (three weeks) into two young infants under my care, both suffering from malnutrition, with the idea that it would afford a means of combining what blood sugar they had with the tissues in order to improve their condition.

Neither child had previously exhibited signs of carbohydrate intolerance or the experiment would not have been attempted. It would not have been safe. At the time of the experiment they did not vomit, retaining all of the food.

Case I.—The first child, baby D., a malnourished baby of four months, who had been for months in the hospital without gaining much and having a high carbohydrate ingestion and retention, and a blood sugar of eighty-four, was given a daily dose of one unit of insulin for seven days. This was administered the same time that his ten o'clock bottle was given. A prophylactic dose of glucose was given with the first dose, to act as a buffer. His diet was a malt soup preparation with whole milk diluted with water in equal parts, also three drams of melted butter. His caloric intake was sixty-five calories a pound a day.

On the seventh day five hours after his dose of one unit of insulin, he fell into a hypoglycemic collapse, from which he was revived by the administration of sixty grams of glucose by mouth. After all of the previous doses of insulin, the pulse rate was not increased. From the beginning he at once began to gain in weight and seemed happy and contented, being rosier and fatter. In sixteen days he gained sixteen ounces, and his condition was much improved. His blood sugar, four days after the stopping of the insulin, was eighty. He took a daily ration of orange juice, one ounce, in addition to his bottles.

Case II.—Baby B., an undernourished child of five months who had been admitted to the wards because of uncontrollable vomiting, was for this reason fed upon large doses of farina and skimmed milk. His intake was eighty calories to the pound daily, upon which he slowly gained in weight but still was undernourished. He suffered from colic and for this citrate of soda was given in his total food, which was boiled before administration, and vomiting ceased. He also took one ounce of orange juice daily.

After a few days of insulin treatment, I felt that it was only fair to the child to have his milk increased in caloric value and his stomach being retentive I used whole milk instead of skimmed diluted with water as before.

His stools became smooth and colic disappeared. He received a daily dose of one unit for a few days with his ten o'clock bottle. A prophylactic dose of glucose was given with the first dose. He suffered from no shock, but being feeble I reduced the dose of insulin to half a unit. The administration caused no increase in the pulse rate at any time; in seven days his weight increased fifteen ounces. Four days after the insulin was discontinued his blood sugar had risen to 104 (twenty-four milligrams above normal for children). Banting had the same experience with rabbits after discontinuing the administration of insulin.

I made sure that the children did not vomit their food, that they had a large carbohydrate buffer against the blood sugar reducing insulin. How much pancreatic insufficiency plays a rôle in inanition and athrepsia no one can tell; the pancreas, no doubt in common with other organs, is depressed. Perhaps some of the vomiting, distention, and much of the tissue wasting in these cases are due to this default. I presumed that this was the case in these children and therefore gave the insulin.

Under no circumstances should it be used without a large buffer of carbohydrate in the diet or in the blood. While these two cases present scanty data, I report them nevertheless for what they are worth.

Minute doses of insulin given with every bottle might be of some value in many cases of athrepsia. It might be worth trying in selected cases, in an institution where blood sugar estimations can be done frequently and other observations made which would be needed in such cases. It might be considered that I have performed a perilous experiment. It did not prove so, however. The experiment was stopped because I felt that change in diet was needed, and if this was done, the results could not be interpreted as due to insulin.

The Familial Concurrence of Diabetes Mellitus and Canities Prematura

By HUGO W. TRAUB, M.D.,
Chicago.

Under the influence of the rediscovery of Mendel's forgotten observations by de Vries, Tschermak and Correns less than twenty-five years ago, the factor of heredity in human pathology assumed a new aspect. As the true significance and potentialities of Mendel's great discovery gradually began to break through the carefully cloistered walls of workers in the purely biological sciences, it became apparent that not only would it bid fair tremendously to influence the biological, but the social and political sciences as well.

Sufficient evidence has accumulated to enable one to say that the long known and daily observed fact of heritable qualities and tendencies in organic nature has become to some extent at least susceptible of measurement. This possibility of quantitative treatment must of necessity recast many commonly held notions concerning the relative weights of the socalled exogenous and endogenous factors in the etiology of human disease. In an era still dominated by the genius of Pasteur, this has probably its best expression in a tendency on the one hand to a renewed study of the organism as a whole, that of the constitution or the diathesis concept, or a pure anthropological viewpoint which Paulsen attempted to introduce—the other a renewed focussing of the attention on the original germ cell from which the latter must have proceeded.

Eight years ago two members of a family came under my observation in whose family history diabetes appeared to be an uncommonly frequent affection. The actual incidence was not positively known. Inasmuch as I had the cooperation of an enlightened interest and as it appeared probable that some accurate data might be obtained, I undertook the collection of the complete pedigree.

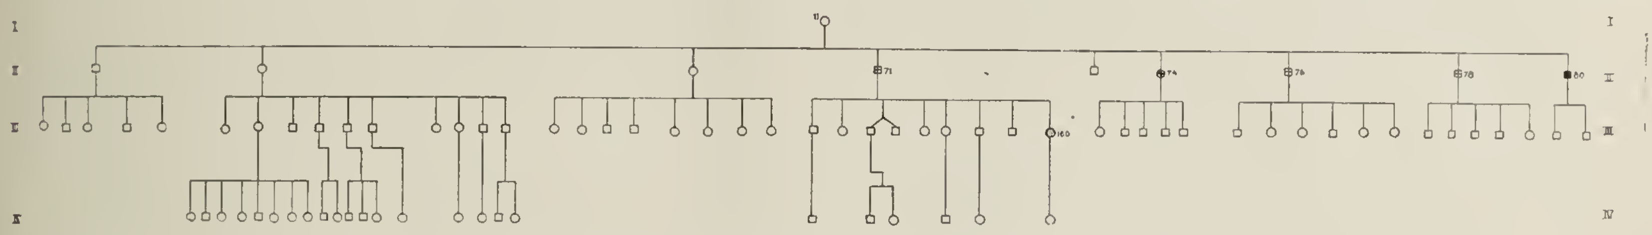
Incident to the collection of these data, it was casually learned that another member of this family who had subsequently died of diabetes, had become strikingly white haired at the age of twenty. When it was later on disclosed that other members of the family had become grey haired while very young, it was decided to investigate this point as well as some other things.

And while the details and proposed statistical treatment of this study, when finally completed, are reserved for another place, let it be said here that I am well aware of the criticism—this not entirely ill founded—of certain experimental geneticists of the scientific value of all such work. While the possible sources of error are somewhat wider than in conventional laboratory work, if certain precautions are taken many of these are avoidable. Chief among such are utter disregard of time and a stubborn insistence on accuracy among one's collaborators, on whom one is necessarily dependent. The biographical data herein used were subjected to the closest scrutiny, and agreement on each pertinent datum from at least two independent sources was required for acceptance.

In the accompanying diagrams is shown the incidence of unquestioned cases of diabetes and of well-marked premature greyness of the hair. For the latter I have so far been able to obtain in three instances at least photographic evidence of this condition in individuals long dead; for the former, while the strict anatomical proof of the beta cells of Allen cannot be furnished, an adequate clinical history has been exacted.

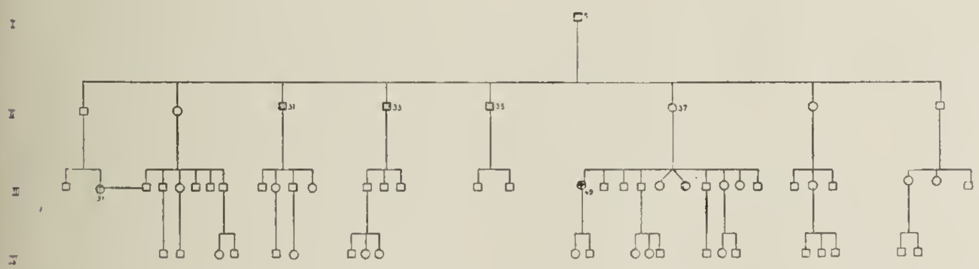
A pedigree showing four generations of descendants of one common ancestor born in 1777, is presented. In this group the first three generations are complete; the fourth being the present children generation, is necessarily a probably growing quantity. As will be noted, the F.1., (first filial) generation consists of seven persons, concerning all but one of whom, all desired data were secured. Three of these were prematurely grey. Inasmuch as all of these persons were born prior to the year 1822, it is very unlikely that—in view of what is known concerning the historical development of the clinical concept, diabetes,—that, even though the same had occurred, it would have been recognized. It has seemed preferable, therefore, to assume nothing more concerning the point.

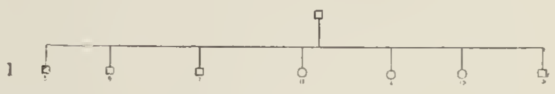
The F.2. generation consists of forty-four individuals, concerning twenty-five of whom all desired data were obtainable. Here we note in the children of I.5. the marked hereditary influence of canities prematura, four of eight having been affected. One of these four, moreover, manifested diabetes, to which he succumbed at the age of sixty-eight. We find, further, among the children of I.9 no canities, but on the other hand one case of diabetes in the only female in that particular group. Death occurred at fifty-six. We next find that among the nine children of I.11, there occurred five cases of diabetes, four having died of diabetes and its complications at the ages, forty-nine, sixty-four, forty-nine, forty-four, respectively, one still surviving. In one member of this particular group (II-80), we note for the second time in the F.2. generation the curious precession of diabetes by the most striking example of canities prematura. Sufficient reliable information concerning the descendants of I.7 and I.1 is still unfortunately lacking, both of these groups being of especial interest owing to the premature greying of the two forebears, as shown.



In the F.3. generation, numbering 148 individuals, concerning 103 of whom all desired data were obtainable, there are two genuine cases of canities prematura, as indicated. One case of diabetes has recently been uncovered, this woman being, as will be noted, the daughter of another who was completely white before attaining the thirtieth year and who had been positively free from diabetes, but succumbed to carcinoma of the breast. It is an ironical coincidence that this same woman—one of two persons most helpful to me in the collection of her family data—was herself within the past year found to have diabetes, only after she had been for a time chiropractically abused for a supposed sciatica. The present mean age of the F.3. generation, however, has not yet attained the period of maximum incidence for the development of diabetes, while it has for the appearance of premature greyness.

The F.4. generation consists entirely of children, none of whom exceeds the age of fifteen, and does not for the present interest us. There is no instance thus far of the occurrence of a case in a juvenile.





The existence of a hereditary or familial factor in the etiology of diabetes has long been known. Blumenbach is credited with first having noted it, and Külz, "whose work fills one third of all the tomes on diabetes," observed a familial influence in approximately one fifth of his cases. With this value a number of statistically treated series are in close agreement, and as a general thing there is no dearth of recorded observation concerning this factor.

However, this is true not nearly to the same extent as premature greying of the visible hair. This is probably due to our being so accustomed to the normal involutional process, that when the scalp and beard hair whitens earlier than is the normal experience, we accord this little clinical significance, if any at all, or indeed regard it as a curiosity. That canities generally may have a physiological mechanism and significance, quite at variance with what has been believed, is suggested b ythe work of Bloch.

It is the present purpose to attempt a theoretical correlation of the familial occurrence of diabetes mellitus and of canities prematura in the same human stock. Of the several possible feasible methods, two suggest themselves: 1, a mendelian manner of treatment, which presumes completeness of data and involves complicated mathematical considerations, usually meaningless to clinicians; 2, one founded on pathological physiological considerations of a biochemical rather than a structural character.

To gain a proper perspective, it cannot be amiss in this connection to set forth the accepted current views, both of the probable ultimate and essential character of diabetes mellitus, and that which is and has long been held to be the intrinsic nature of canities. As for diabetes, Allen, its foremost modern experimental student, has cleared the air and the literature by sharply separating experimentally derived fact from armchair fancy. On the basis of strict experimental considerations he defines the anatomical basis of diabetes to consist of a "hydropic degeneration of the beta cells of the islands of Langerhans, which is specific and due solely to overstrain of the cell function by diets in excess of a weakened assimilative power." Anent the pathogenesis he says: . . . "the humoral stimulus to hydropic degeneration . . . therefore cannot be the excess of blood sugar, but must be something deeper or more specific in connection with diabetes. Though only traces of their internal secretions can be supposed to exist in the blood, it is conceivable that the islands may be sensitive to a deficiency of the circulating hormone itself. This question which suggests a secretory regulation by a principle resembling mass action, as also the possible nervous control by the intrapancreatic ganglia, are matters of pure speculation at present." Allen finally takes his stand with v. Noorden and Martius, when he declares that "existing knowledge warrants dismissing old myths of constitutional or pluriglandular degeneracy" . . . "diabetics should be regarded as normal individuals, who have become afflicted with a definite organic disease." But nevertheless the very fact that there is something—predisposition or call it what we will—which seems to be transmitted more particularly only by and to certain individuals in whom diabetes develops, while in others under similar conditions it does not, justifies the attempts of those committed to a mendelian or other mode of thinking to interpret or seek the ultimate pathogenesis in mendelian or some other terms.

Concerning canities—and more particularly its premature and aberrant forms—we find much more unanimity in the systematic presentation of its clinical behavior than concerning its pathogenesis. Moreover, while one regularly finds various cutaneous complications described in the systematic clinical accounts of diabetes, changes in the cutaneous appendages which might be reasonably expected as well, are not mentioned in the readily available literature of the past fifty years. Von Norden's account of a remarkable change in the form of the scalp hair of one patient is the one exception I have been able to find. Dermatologists are in accord on three points which seem to me to have a direct bearing on the present problem: 1., there is a marked hereditary element in the premature form; 2, there is a disturbance in pigment metabolism; 3, the hair cortex contains gas bubbles. The pigment phase of the question has recently been attacked in a novel manner by Bloch. The "dopa" reaction (dioxyphenylalanin) developed by him and the theory founded thereon offers not only a rational explanation of the mechanism involved in the production of canities but opens a wide field for experiment and speculation. Physiologists have long known that certain enzymes play an important rôle in the oxidation and reduction processes of living organisms, and while enzymes are probably present in every cell of the body (Wells), the specific function of but very few of these has been definitely determined. Bloch believes that he has discovered the function of an enzyme, named by him dopa oxydase, normally contained within the basal cells of the epidermis and those of the hair matrix, in which pigment formation is generally believed to take place. Bloch and his coworkers have demonstrated that the production of melanin is due to an oxidation process locally initiated or accelerated by this enzyme in a mother substance or propigment present in the general circulation. This propigment he believes to be dioxyphenylalanin or a body, closely related structurally to tyrosin, which in turn numbers adrenalin among its very close chemical relatives. That melanin and adrenalin are chemically related substances is of course not a new observation; but it seems a curious coincidence that melanin is so related to a body, whose capacity for the artificial production of glycosuria is well known.

The presence of gas bubbles—more often referred to as air bubbles—in the cortical and medullary substance of the whitened hair shaft has recently again been confirmed in a study of what is possibly a rare variant of canities by Cady and Trotter. While these investigators do not so term the hair anomaly which they studied (ringed hair) and while they conclude that pigment atrophy does not enter into the pathogenesis of that condition, it is of more than passing interest that the nature of the socalled gas globules within the hairshaft engaged their attention. While their further conclusion that these gas globules are probably carbon dioxide does not exactly fit the hypothesis that canities is due fundamentally to a failure of an oxidation process to take place, it will at least tend to furnish a more rational viewpoint than that of the old stereotype, implying that atmospheric air has in some mysterious manner entered the hair shaft.

But what has all this to do with the pathogenesis of diabetes and what conceivable relationship can exist between these two conditions? There have occurred to me at least two means of possible correlation. The one has to do with another well known, just as little understood, but in some respects analogous, heritable process—and one in which a specific enzyme is generally accepted as playing a rôle of considerable importance. Hemophilia, according to Vines, is a ferment deficiency disease, and Osler declares the deficiency to be "on the organic side of the clotting mechanism and not on the inorganic, as, e.g., due to lack of calcium salts." In the light of Allen's previously quoted suggestive remark, relative to an as yet unknown more deep seated factor whose absence or presence induces or inhibits changes in carbohydrate metabolism after the manner of a catalyst, it would seem permissible to think at least of some such mechanism in the ultimate pathogenesis of diabetes. The isolation of insulin brings the solution one definite step closer, but it is obviously not equivalent to a *causa causans*. Whatever this latter may be—whether a substance normally held in physiological balance, or an abnormal one—it is selfevident that in either event it must have its origin somewhere, and this probably extrainsular.

But this does not aid us in interpreting the greater susceptibility of only certain individuals or of certain groups to the development of diabetes, to canities, or for that matter, greater predisposition to noninfectious degenerative processes of unknown origin generally. But while it may appear going somewhat far afield to do so, we find a second possible key in some recent investigations by Guyer of a fundamental biological problem—the doctrine of the noninheritance of acquired characteristics. While this latter is generally considered settled *ex cathedra* —save among a small but aggressive group of neo-Lamarckians—Guyer has once again been led to approach the same through his work on the possible influence of immunity reactions in biological variation. Briefly stated, Guyer and his coworker, E. A. Smith, have been able to show that normal pregnant rabbits, injected with food serum immunized to rabbit lens, can be caused to produce young with certain eye defects. "The most interesting thing," I quote Guyer, "about the experiment was the fact that the eye defects were transmissible to subsequent generations, and inasmuch as the condition could be passed down through the male line alone, it is evident that it is based on changes in the germ cells." We have presented to us then, the "possibility of inducing, directly or indirectly, germinal changes by means of antibodies developed in an animal's own body against tissues taken from individuals of the same species." But not this alone; Guyer showed that "an animal can on occasion produce antibodies against its own tissues when these have become displaced or altered, and that such antibodies can directly or indirectly affect the germ cells." While it is perhaps not possible for me here to do justice to the true inwardness and the conceivable implications of Guyer's significant observations, they are—as a means of furnishing an insight into certain fundamental biological and therefore medical problems—in themselves worth inviting attention to. Moreover, as to their more particular application to the problem in hand, it is of course not possible, owing to our ignorance of the essential nature not only of immunity reactions generally, but of what has been called the "endocrine formula," to do more than to speculate. Nevertheless, the suggestiveness of changes which are capable of being induced in the protein molecule of the gonads remains, and the experimental zoologist and the biochemist may perhaps show us just what, in concrete terms, such apparently unrelated things as diabetes mellitus and premature greying of the hair have pathogenetically in common.

The author's references will appear in his reprints.

The Prescribing of Diabetic Diets

By EDWARD E. CORNWALL, M.D., F.A.C.P.,
Brooklyn,
Attending Physician, Norwegian and Williamsburgh Hospitals, Consulting Physician, Bethany Deaconesses and Broad Street Hospitals.

In the treatment of diabetes regulation of the diet is essential, and there is no reason to doubt that it will always be so. Valuable as insulin may be as a palliative and emergency remedy, it can not obviate the necessity for dietetic regulation, though it may increase the effectiveness of particular diets; in fact, the use of insulin calls for increased care and precision in dietetic regulation. A large proportion of the cases of diabetes ordinarily met with can be treated with a considerable degree of success and comfort by regulation of diet alone.

The dietetic treatment of diabetes has undergone rapid development in recent years without approaching very near to finality. A few years ago this dietetic treatment was limited to restriction of carbohydrate. Then fat was pronounced almost as bad as sugar in the diet, and the dangers of acidosis were emphasized, and we were given safeguarding antiketogenic glucose fatty acid ratios to govern the construction of the diet. Then we were told that a diet with a high fat and low protein and carbohydrate content could be taken without producing acidosis. Widely taught was the doctrine of prolonged starvation and undernutrition. And there were special diet cures, as the oatmeal cure, the potato cure and the milk and buttermilk cures; and diets were recommended in which protein from milk and eggs was favored generally over that from animal flesh. The diabetic dietetic therapeutic needle has pretty nearly boxed the compass.

It is probable that in all the teachings above alluded to some elements of truth may be found; and it is certain that the dietetic treatment of diabetes is too complicated to be standardized; no set or system of diets nor any rigid plan of treatment can suffice; every case is an individual problem. But something to serve as a basis of treatment and a simplified technic for adjusting diets to conditions are possible and desirable.

In the following presentation I deal with the technic of dietetic prescribing in diabetes rather than with the particular treatment of that disease. The prescribing of the diet is the first lesson in diabetic therapeutics which the physician must learn. It is true that the physician often relegates the actual work of arranging a suitable diet in accordance with his recommendation of certain quantities of protein, fat and carbohydrate, to a dietitian, and if the latter has the proper knowledge and experience the result may be satisfactory; but the responsibility rests on the physician, and it behooves him to know how to prescribe the diet himself. A statement of certain amounts of protein, fat and carbohydrate to be allowed the patient does not in itself constitute a dietetic prescription, but only a suggestion to be followed in the making of the prescription. Many other things must be taken into account. There is the fact that all forms of protein are not of equal value in the diet; a protein ration made up of gelatin would be worthless, and one made up of gliadin would be inadequate; and of the animal proteins which alone are perfect proteins and supply easily the nutritional requirements of the body, those provided in some food articles are more suitable to some cases than those provided in other articles. The matter of the digestibility of articles containing food principles may require consideration. The matter of the nonprotein nitrogen content of foodstuffs may possess importance in some cases; the freedom from nitrogenous extractives of milk curd and its lesser susceptibility to undesirable bacterial action in the alimentary tract, especially when given in the form of acid cottage cheese, as compared with flesh, may possess therapeutic significance in some cases. Eggs may possess advantages in some cases and disadvantages in others. The matter of the fats in the diet may call for special consideration of properties and physiological reactions, especially when large quantities have to be given. In order to supply sufficient vitamines, especially of the water soluble varieties, in cases compelling severe restrictions, it may be necessary to practice close selection of foodstuffs. And there is always the alkaline balance to be considered, which may require, in addition to maintenance of the normal alkaline excess in the diet, that extra alkalies be given to offset a pathological acidotic tendency. And it must ever be borne in mind that individual cases differ in ability to digest, assimilate and metabolize, and that other factors besides the diabetic condition may govern the dietetic prescription, and that some of these factors may not affect the protein, fat and carbohydrate requirements as such, but rather the character of the articles in which those food principles are supplied to the patient.

The particular dietetic treatment, which is highly individual, must to a large extent be taught to the physician by his own experience. I desire here to avoid that phase of the subject; but it is impossible to avoid suggesting a certain amount of didactic therapeutics when describing definite diets. The fact that the diets given here are definite and contain particular articles, and the fact that they are placed in particular series, are therapeutically suggestive. Such therapeutic suggestiveness is conceded provided that it be borne in mind that these diets are intended only to serve as a basis for individual treatment, and that no specific effect is claimed for them.

ARTICLES OF FOOD USED IN DIABETIC DIETS.

For convenience in prescribing it is desirable to have the list of articles of food regularly used in diabetic diets comparatively small, but it must be large enough to permit of balanced rations and to allow for a reasonable regard for variety and palatability. Additions to set lists of foods can always be made by special order. In the diabetic dietaries described here the list of foods, while not large, is reasonably comprehensive. Regard for digestibility and general wholesomeness obtains in the selection. The varieties of animal flesh mentioned are limited to the most digestible and wholesome and otherwise desirable of those which are common. While some of the vegetables and fruits mentioned may be difficult of digestion for particular persons, they are generally wholesome, and choice is always possible.

To facilitate prescribing, group names are used to a considerable extent, taking advantage of the fact that many articles of the same class have approximately the same food value. This is particularly the case with the vegetables containing about one gram of carbohydrate to the ounce or thirty-gram portion, with approximately equal protein and fat content. These vegetables are referred to as Vegetables I. cooked and Vegetables I. raw. Vegetables containing two grams of carbohydrate to the ounce are similarly grouped. Vegetables containing more than two grams of carbohydrate to the ounce are left for special order. Fruits are similarly grouped. Certain flesh foods, with obvious fat removed, are grouped under the name, Meat lean. Likewise a selection of fishes which have very little fat, are grouped under the name, Fish lean. A selection of nuts which have approximately equivalent food values are listed as Nuts. The cereal porridges from the various grains are grouped under the names of the grains. Other articles are listed under their proper names.

Lists of articles of foods which the author has found sufficiently large to meet most ordinary needs of dietetic prescribing in diabetes are given in the diabetic dietary (1) and the universal diabetic diet list (2).

CONSTRUCTION OF ORIGINAL DIETS.

The diabetic dietary and the universal diabetic diet list are used in the construction of original diets. The former gives selected articles of food arranged in groups according to the carbohydrate content of one ounce or thirty gram portions and some other considerations. The protein and fat content and caloric value of the one-ounce portions of each article are also given. The groups are arranged in regular order, according to their carbohydrate content, from Group I., which contains no carbohydrate, to Group X., which contains twenty grams of carbohydrate to the ounce.

UNIVERSAL DIABETIC DIET LIST

In Each Portion P	F	C	Cal.	Total No.	PORTIONS GM	OZ		Number in Meals B	D	S	L	EXPLANATORY
gm	gm	gm										
3	0	6	35		180	6	Vegetables I, cooked...					**VEG. I.** cooked Spinach, string beans, celery, asparagus, marrow, okra, pumpkin, dandelion tops, leeks, beet tops, tomato, cabbage, cauliflower, wax beans, sea kale, sauerkraut, brussels sprouts, chard, kohl rabi, egg plant.
2	0	4	25		120	4	Vegetables I, raw					**VEG. I.** raw Endive, lettuce, cabbage, celery, tomato, cucumber, radish, watercress.
3	0	12	60		180	6	Vegetables II, cooked					**VEG. II.** cooked Carrot, squash, turnip, onion, beet.
2	0	8	40		120	4	Vegetables II, raw ...					**VEG. II.** raw Onion, turnip.
0	0	6	25		180	6	Fruit I					**FRUIT I** Grapefruit, lemon, strawberry, tomato.
0	0	12	50		180	6	Fruit II					**FRUIT II** Orange, peach, watermelon, muskmelon, pineapple, sour apple, blackberry, cranberry.
3	1	12	75		90	3	Oatmeal porridge					**OATMEAL PORRIDGE** Made plus four water.
3	0	18	90		90	3	Potato					**WHEAT PORRIDGE** Cream of wheat, farina, etc., made plus four water.
3	0	18	90		90	3	Rice, boiled					**COTTAGE CHEESE** From skimmed milk without addition of cream or butter.
3	0	18	90		90	1	Bread					**FISH, LEAN** Haddock, flounder, cod, bass, trout, pike.
4	1	20	100		120	4	Maccaroni, boiled					**MEAT, LEAN** Mutton, beef, lamb, with obvious fat removed. Also poultry.
4	0	20	100		120	4	Wheat porridge					**CREAM** 20 percent. fat.
1	0.5	5	30		One		Cracker					**NUTS** Butternut, pecan, pignolia, walnut, brazilnut, filbert, hickorynut, almond.
12	1	2	60		60	2	Cottage cheese					**COCOA SHELLS, COFFEE, TEA** Clear infusions.
12	12	0	150		Two		Eggs					**EXTRA ARTICLES** In portions of one ounce, 30 grams.
24	0.5	0	100		120	4	Fish, lean, cooked					
24	15	0	225		90	3	Meat, lean, cooked					
12	16	0	200		45	1.5	Cheese					
8	8	12	160		240	8	Milk					
6	1	4	50		Six		Oysters					
0	12	0	110		15	0.5	Butter					
0	15	0	135		15	0.5	Olive Oil					
5	15	0	150		30	1	Bacon, fried					
1	6	1	60		30	1	Cream					
0.5	4	1	40		30	1	Olives					
4	9	1	100		15	0.5	Nuts					
0	0	0	0		q	s	Cocoa shells, coffee, tea					
0	0	0	0		180	6	Broth					
0	0	0	100		30	1	Whisky					

In using the diabetic dietary the quantities in grams or ounces of each article or group prescribed in the daily ration is written in the space opposite the name of the article, or against the group or part of the group inclosed in a bracket. The computation of the food value of the daily prescription is made by multiplying the number of ounces of each article or group by the proper figures and adding up. The articles and quantities in the daily ration can be distributed in the different meals by the prescriber, or that can be left to the patient to do. This diabetic dietary is somewhat simpler and more flexible than the universal diabetic diet list, but it is inferior to the latter in facility of use, and I have come to prefer the latter in my own work.

SPECIAL ORDERS

EXPLANATORY

The quantities are given in grams and ounces, the figures for the latter being in parenthesis.

Cocoa shells, coffee, tea. Clear infusions.

Vegetables I cooked. Spinach, string beans, celery, asparagus, marrow, okra, pumpkin, dandelion tops, beet tops, tomato, leeks, cabbage, cauliflower, wax beans, sea kale, sauerkraut, brussels sprouts, chard, kohl rabi, egg plant.

Vegetables I raw. Lettuce, endive, cabbage, celery, tomato, cucumber, radish, watercress.

Vegetables II cooked. Carrot, squash, turnip, onion, beet.

Vegetables II raw. Onion, turnip.

Fruit I. Grapefruit, strawberry, tomato, lemon.

Fruit II. Orange, peach, watermelon, muskmelon, pineapple, sour apple, blackberry, cranberry.

Oatmeal porridge. Made plus four water.

Wheat porridge. Cream of wheat, farina, etc., made plus four water.

Cottage cheese. Made from skimmed milk without addition of cream or butter.

Fish lean. Haddock, cod, flounder, bass, trout, pike.

Meat lean. Mutton, beef, lamb, chicken with obvious fat removed.

Cream. Twenty per cent. fat.

Nuts. Butternut, walnut, hickorynut, pecan, filbert, almond, pignolia.

Directions for using the Composite Dietetic Prescription.

To get a particular numbered diet from the Composite Prescription, take all the articles before whose names are placed the number of the desired diet and numbers lower than that; or omit all articles before whose names are placed numbers higher than that of the desired diet.

To get a particular lettered diet, take all the articles before whose names are placed the letter of the desired diet; or omit all articles before whose names the letter of the desired diet is not found.

Omitted articles may be scratched if the Composite Prescription is used as an original prescription.

Vegetables II and Fruit II may be substituted for Veg. I and Fruit I in half the quantities. Substitutions and additions may be made of Approximate Equivalents and of other articles by special order.

APPROXIMATE EQUIVALENTS

A. P.0-2, F.0-1, C.9-10, Cal. 45-60.
Bread, 15 (½)
Potato, 45 (1½)

The quantities are given in grams and ounces, the figures for the latter being in parenthesis.

*Reprinted from *Diabetic Diets, with a Universal Diet List, E. E. Cornwall, M. D. Connell Press, Brooklyn, N. Y.*

The universal diabetic diet list presents a selection of articles of food for use in diabetic diets, given in arbitrary portions, the quantities of which are stated in grams and ounces before the names of the articles, together with their approximate protein, fat and carbohydrate content and fuel value. Group names are used to a considerable extent in describing the articles of food, the significance of which is given in accompanying text. The use of arbitrary portions of varying amounts instead of uniform quantities, as in the diabetic dietary, has the advantage of making for uniformity in the portions of the same things served at different times.

In prescribing one or more portions, or a fraction of a portion, the proper numeral is written in the blank space which lies opposite the name of the particular article and in the column under the letter designating the meal at which it is taken (B for breakfast, D for dinner, and SL for supper or lunch, etc.). The total number in each case is then summed up in the column of total number of portions. Or the total number of portions of each article prescribed in the daily ration is first stated in the column for total number of portions and then distributed among the different meals. The latter method is usually found most convenient.

The carbohydrate ration is first provided for, chiefly from the carbohydrate group of food stuffs, which is the first group in the list. The articles in this group contain small or negligible amounts of protein and fat.

Next, the protein ration is provided for, chiefly from the protein group of food stuffs, which is the second group in the list. The articles in this group contain little or no carbohydrate and varying amounts of fat.

Next, the completion of the fat ration is provided for, chiefly from the fat group of food stuffs, which is the third group in the list. The articles in this group contain little or no carbohydrate and varying amounts of fat.

Beverages and stimulants are also provided for.

To get the food value of a daily diet thus made out, the totals of the number of portions of each article of food prescribed, as found in the column of total number of portions, are multiplied by the food values of one portion as found before the name of each article. The numbers so obtained are written on a separate piece of paper, and the columns of figures representing the protein, fat and carbohydrate content and caloric value of the different articles in the prescription, are summed up. These sums give the food values of the prescription. If, in this summation, any of the food values of the diet as made out fall short of the food values desired, it is easy to make such additions as may be necessary; in fact, in making out a diet, it is good practice to make a first tentative diet which will fall somewhat short of the desired food values, and to add to it what may be found necessary after the food value of the tentative diet has been estimated.

The variety of food stuffs permitted in the universal diabetic diet list is sufficient for the essential needs in a large proportion of cases, but greater variety may be desirable, and can be secured by the use of substitutions. These substitutions are indicated in the blank space at the foot of the list. The substitution may be of single articles or of groups of articles in the list of *approximate equivalents* (2), or of that list in general, or of articles outside that list. Groups are indicated by their designating letter.

The diet thus made out, while perfectly intelligible, is conveniently copied in conventional menu form for the patient: running the eye down the columns marked for breakfast, dinner and supper or lunch, the articles for those meals are brought together in menu form, but with quantities translated from the portions of the list to grams or ounces. Special orders for substitutions are written in connection with the articles to be substituted for or at the bottom of the page.

THE USE OF PARTICULAR DIETS AS A BASIS IN PRESCRIBING.

Although no rigid plan of treatment is applicable in diabetes, it is often found convenient to use a series of definite diets as a basis for individual treatment. A series is here presented of sixteen definite diets, any one of which can be taken as a point of departure for modification to meet individual needs. They are all balanced, so far as the quantities permit, and all contain fat rations well within the limits of safety indicated by the generally accepted antiketogenic glucose fatty acid ratios. These diets are arranged in two series, of which one, the numbered series, can be used for ascertaining the tolerances, and the other, the lettered series, for gradual starvation to reduce the glycosuria and hyperglycemia, in accordance with the general plan advocated by Joslin. The diets are purposely made very simple in structure. The articles of food used in them are limited to a comparatively small number, greater variety being allowed by the use of the approximate equivalents and of other specified equivalents. Uniformity in the size of the portions generally obtains, and the portions conform generally to those of the universal diabetic diet list. Group names are used which conform to those of that list, for whose understanding the explanations given in that list are necessary. The sixteen diets are all presented in one composite dietetic prescription (2).

Directions for prescribing particular diets of the series through the composite dietetic prescription, accompany the latter. Independent variations starting from any one of the series are easily made. Using the composite prescription, they may be made by adding new articles in the space below the prescription, under the head of special orders. As for example: If Diet No. 9 has been prescribed satisfactorily, but for some reason the prescriber does not wish to give No. 10, but some other modification of No. 9, he can write at the bottom of the prescription, the direction to add to specified meals, the articles of food and the quantities necessary to make the desired modification. It often happens that the carbohydrate, fat or protein ration of a stated prescription, has been increased as much as seems advisable in the case, while it is desired to increase further the rations of one or both of the other two food principles. Instead of making additions by special order, as above described, the same object may be accomplished by scratching some of the articles belonging to a set diet of higher number than that of the one of which the special modification is to be made, and leaving unscratched other articles belonging to the higher numbered diet, whose addition makes the desired modification. The composite dietetic prescription and universal diabetic diet list are conveniently used printed on separate sheets.

Considerable latitude for variety is allowed by the list of articles mentioned in the explanation of the group names used, and more provision for variety is found in the list of approximate equivalents. In the use of the latter (by special order at the bottom of the prescription), any particular group of approximate equivalents may be allowed in place of a particular article in the diet, as for example: approximate equivalents A may be allowed in place of one-half ounce of bread; or a specified number of groups of approximate equivalents may be allowed wherever they fit in, as for example: Approximate equivalents A, B and C may be allowed as indicated; or there may be particular or general allowance of these equivalents with special restrictions, as for example: Approximate equivalents D, E, F and G may be allowed provided there is no increase (or a specified increase), in the rations of meat and bacon, and provided there is no increase (or a specified increase) in the ration of fish. Such examples show how the approximate equivalents may be used. Any single article may be added to any meal by special order.

GENERAL SUGGESTIONS.

In the average case, the first thing to do is to clear the urine of sugar. For this purpose, partial or gradual starvation is preferred. Severe cases which resist a considerable degree of starvation may be given insulin.

After the urine is sugar free, the carbohydrate tolerance should be ascertained by gradually increasing the diet. In this process the protein ration can usually be raised to meet the basal protein requirement very quickly. The basal protein requirement for adults is taken to be two thirds of a gram or one gram of protein per kilogram of body weight, and for children about two grams.

The carbohydrate tolerance is found by gradually increasing the carbohydrate in the diet until sugar again appears in the urine.

The fat ration is usually increased slowly while the carbohydrate tolerance is being determined, and then it is increased sufficiently to supply the basal metabolic requirement. The basal metabolic requirement for the patient at rest is found by multiplying his weight in kilograms by thirty.

After the carbohydrate tolerance is found and the basal metabolic requirement satisfied, that is, after a subsistence diet has been achieved, the fat is increased, and possibly the protein also in some cases, so as to supply enough calories to enable the patient to lead a more active life than is possible on the subsistence diet.

In increasing the fat ration the safeguarding antiketogenic glucose fatty acid ratio must be borne in mind. This ratio fixes a limit to the amount of fat which can be taken with a given amount of carbohydrate without regularly producing acidosis. The figures for this ratio have been variously stated. A widely accepted statement of it has it as one to one and five tenths, counting as glucose all of the carbohydrate, with fifty-eight per cent. of the protein and ten per cent. of the fat, and counting as fatty acid ninety per cent. of the fat and forty-six per cent. of the protein. Another statement of it which is favored by good authorities has it as one to three, counting as glucose all of the carbohydrate with sixty per cent. of the protein, and as fatty acid all of the fat. The limits set by these ratios are not always found to insure against acidosis.

In cases which can not take care of the basal metabolic requirement, and also cases which can not take care of a diet sufficient to meet the energy requirements of the mode of life desired, insulin may be given. The pathological examinations which are essential are these: examination of the urine for glucose and ketone bodies, estimation of the blood sugar, and perhaps estimation of the carbon dioxide of the blood plasma.

The Pancreas and the Interrelation of the Endocrine and Sympathetic System in Regard to Diabetes

By C. LEGIARDI-LAURA, M.D.,
New York.

As pointed out by no less an authority than Joslin (1), insulin does not cure diabetes and the matter of diabetes treatment is still an open one. Important as the discovery of insulin appears to be, I do not believe that it materially changes the question of the rôle of the pancreas in diabetes. In fact, except for a stronger determination in the present researches, I do not see any fundamentally new fact arising from the Canadian experiments. The production of an alcoholic pancreatic extract from the normal pancreas as is done now by Banting and his coworkers, brings the problem at exactly the same stage at which it was brought by much earlier experimenters, i. e., fifteen to twenty years previously. The results obtained by the discoverers of insulin are practically the same as the results obtained by Minkowski (2), Lanceraux, and Hedon (3) since 1898 with the subcutaneous transplantation of the pancreas. The same results have been obtained in 1908 by Zuelzer, Dohm and Marxer (4) with pancreas extracts, *videlicet*, a diminution in the elimination of sugar and acetone bodies and an improvement in the general conditions. But then as now the results lasted only as long as the administration of the extract was continued and no active increase of the animal's own metabolizing capacity was determined by the treatment.

So that the same objections apply to the present experiments as to the earlier ones, which were conducted under the guide of the same biological principles (5).

No one will question, by this time, the important part played by the pancreas in sugar metabolism. But this knowledge must be coordinated with all the other factors of this complicated problem.

In other words, the latest discoveries about the pancreas do not destroy all that has been done before, beginning with the works of Claude Bernard on the storing of glycogen by the liver and on the glycosuria resulting from the *piqure* and proceeding with all the experiments with the adrenals, with the thyroid, with the pituitary body, with the sympathetic system, with the kidneys, with the muscles and other tissues.

Let us consider the problem from the point of view of the interrelation of the different elements composing the sympathetic endocrine system. Let us admit, as many facts prove, and as Massaglia, Vassale, Dominicis, Viola, Pende and so many other authors believe, that this entire system works as a unit. Let us assume that the pancreas is the organ most directly concerned in sugar metabolism, as it provides the amboceptors necessary for the assimilation of sugar by the cells. We knew before, and we know still better now, after the works on insulin, that sugar must be present in the blood in a definite amount in order that normal animal life be preserved. Hyperglycemia is harmful: hypoglycemia is dangerous. The pancreas then must provide its hormone to the blood in a regular manner. This presupposes a delicate mechanism of control upon the islands of Langerhans.

What organ or what organs furnish this delicate control of the pancreas? It is not easy to answer this question *a priori*. But what we know about the interrelation of the endocrine sympathetic chain, brings us nearer to the solution. Of course the pancreas represents a midway station in the metabolic route of glucose. The ultimate processes are the utilization of the sugar by the muscles, the storing up of the surplus, the burning up of the needed quantity in the process of oxidation. It is during all the intermediate stages of the metabolic process, before and after the midway stage represented by the pancreas, that the other members of the sympathetic endocrine system play their rôle, all directed of course by the central nervous system. The ultimate phase is played by the tissue cells. Here, as admitted at present, takes place that combustion, that oxidation, that Lavoisier considered as taking place in the lungs (6).

Now what we know about the influence of the thyroid and of the pituitary on sugar metabolism points to these two bodies as the immediate regulators of the pancreatic hormone supply to the blood. The recent work on the thyroid is important in this respect. By thyroidectomy on partially depancreatized dogs or by ligature of the thyroid arteries, glycosuria disappears, thus confirming the previous notion that the thyroid has an important influence on sugar metabolism.

The fact that a serum antagonistic to the pituitary, as proved by my experiments, has made glycosuria and polyuria disappear in a certain number of diabetic patients, proves the same thing in regard to the pituitary. Then it seems rational to formulate this hypothesis: The pancreas furnishes a hormone which acts as an amboceptor and renders sugar fit for cellular assimilation and oxidation: an excess of this hormone in the blood would be very dangerous, as proved by hypoglycemia shock; but such excess is prevented by the presence in the blood of antagonistic or compensatory hormones provided by the thyroid and the posterior part of the pituitary. For several reasons I am inclined to believe that the thyroid control of sugar metabolism is predominant in infancy, and the pituitary in adult life. As we can not ignore the facts concerning the thyroid, the pituitary and other glands on sugar metabolism, we have but two hypotheses. Either we admit that the pancreatic, thyroid, pituitary, adrenal glycosurias are all independent entities, and we have as many independent forms of diabetes; or diabetes is a special disease due to a dysfunction of the pancreas, and all the other endocrine members are either compensatory or regulatory organs. From the point of view of physiology we have no other solution. On the other side, with the aid of this hypothesis we are able to understand well proved experimental facts, which seemed in conflict with the pancreatic theory of diabetes. For instance: the experiments of Cushing, Goetsch and Jacobson proving that in normal animal the injection of an excess of pituitary extract causes glycosuria could not be reconciled with the pancreatic theory except by admitting that such an excess of pituitary extract neutralizes the pancreatic hormone in the blood, and thereby causes glycosuria.

In the light of this hypothesis all forms of glycosuria are related, so that we may formulate this general theory: With a degenerated pancreas and normal pituitary thyroid function we have diabetes. With a normal pancreas and hyperfunction of pituitary thyroid system, we also have diabetes. In both cases we have a decreased amount of pancreatic hormone in the blood.

Pathological findings offer us another explanation of diabetic pathogenesis, but not a practical solution in regard to therapy. Even admitting that spontaneous diabetes is constantly due to a degeneration of the islands of Langerhans, we still are compelled to revert to physiology in order to arrive at a successful treatment, at least until we find a way—which is out of sight for the present—of curing or preventing the degeneration of the islands of Langerhans.

We must revert to physiology because in order to treat diabetes we must rely on the remaining healthy part of the pancreas for the restoration of the patient's health. And we must either substitute the destroyed part of the organ, or stimulate, if possible, the remaining healthy portion of it. The transplantation of pancreas and the administration of pancreatic extracts, including insulin, represents tentatively the first solution. Unluckily the effects of these measures are only temporary. The counteracting of the thyroid and especially of the pituitary hyperfunction offers a second solution. As far as practical results are concerned, the observed facts prove: 1. That antipituitary serum in a considerable percentage of cases acts as an active stimulant to that function or functions of the body upon which sugar metabolism depends. In every case in which the ability of the patient's system to metabolize sugar is decreased but not entirely destroyed, the logical course appears to be the stimulation of the remaining metabolizing capacity. 2. In all those cases of diabetes in which the metabolizing capacity for sugar is completely destroyed, there is no logical hope at present of restoring it. In these cases, as admitted by all investigators, insulin can not cure diabetes, but is nevertheless a valuable means of helping this class of patients along.

The Role of the Spleen in Certain Anemic Conditions*

By ERNEST S. CROSS, MD.,
Baltimore, Md.

The history of our knowledge of the nature and functions of the spleen shows certain unique features, in that variations in the size of the spleen have long been classed among the essential findings on clinical examination, assuming the importance of cardinal points, in diseases such as malaria, leucemia and typhoid fever and yet our actual knowledge of the physiology of this organ is still obscure. One might consider this tardy development in knowledge remarkable in view of the fact that the spleen is a perfectly definite, circumscribed organ, occupying a relatively prominent location among the abdominal viscera and easily accessible to experimental study. There are, however, suggestive reasons for the slow development of our knowledge of the spleen which will be referred to later.

The spleen is a solid organ surrounded by a fibrous capsule which sends trabeculæ into the substance of the gland. The trabeculæ break up into finer and finer branches producing a spongy matrix the interstices of which are filled up by spleen pulp. The organ is exceedingly vascular and is supplied by the largest branch of the celiac axis. As we follow the branching of the smallest arterioles into capillaries we find the intimal cells finally ceasing to form channels and existing as rather large, irregularly placed cells. These modified endothelial cells, with a few supporting cells, make up the bulk of the spleen pulp.

These cells are phagocytic, sometimes remaining stationary in their reticulum and sometimes wandering about; but in either case engulfing various particles, especially weakened red cells. At certain times these cells proliferate and some of this type of cell is always being carried away in the venous blood entering the portal vein to arrive at the liver. The Malpighian bodies are pure collections of lymphoid cells scattered through the spleen, enveloping small arteries and thus obtaining a richer oxygen supply than the rest of the spleen pulp which is bathed in venous blood. The Malpighian bodies produce lymphocytes which break off from time to time and make their way into the spleen pulp also, through which, of course, the blood stream from the splenic artery is constantly filtering.

We must conclude that the spleen in the adult normally destroys red cells through the process of phagocytosis. The question as to whether the spleen produces a ferment with which to hemolyze red cells is not yet finally answered but since destruction takes place within the cells it is unnecessary to postulate a special hemolyzing secretion in the spleen itself. These same phagocytes engulf also bacteria, malarial organisms, etc. Iron or at least altered hemoglobin is prepared for the use of the liver cells. It would seem as if the spleen secreted a substance which activated and stimulated the bone marrow to produce red cells and it is possible that this control over the bone marrow may in some cases be a restraint as of leucocyte production in certain conditions like typhoid fever and malaria which are characterized by leucopenia. This might account for the beneficial action of x rays and radium in leucemia, supposing the stimulation of the splenic cells to check leucocyte production in the bone marrow. It is possible though that the mechanism of this relation between the spleen and the bone marrow, at least as far as the red cells are concerned, may be through the supply and storage of iron rather than through some specific manufactured substance like a hormone.

In the Bradshaw lecture for 1920, Sir Berkeley Moynihan draws attention to the fact that the spleen is not a specialized organ with one or two particularly developed functions but is one of a group of organs more or less interdependent. Failure to recognize this is, perhaps, the chief reason why the splenic functions have for so long remained obscure. Moynihan's conception of the problem is most illuminating in that he considers the spleen to be closely connected with, and in fact a part of, four important systems of the body.

1. The spleen as a part of the hemopoietic or bloodmaking system. Formation of red and white cells takes place in the spleen only during embryonic and early postnatal life as a rule. In infections and leucemia, however, the spleen may take part in the production of white blood cells. The relation of the spleen to the bone marrow has already been discussed.

2. The spleen as a part of the reticuloendothelial system. We have already described the endothelial cells as lying loosely in the reticulum of the spleen pulp. The liver also has certain large phagocytic cells, the star cells of Kupffer which are endothelial in nature. They are known to proliferate after removal of the spleen and they may take up iron pigments. Lymphatic glands also contain phagocytic endothelial cells which multiply after splenectomy. The bone marrow also contains somewhat similar cells. Thus these structures seem definitely related morphologically and we can more easily understand why blood pigment is found in the liver, lymph glands and bone marrow when hymolyzing poisons are administered. It has been found in studying the immune bodies of cholera that the spleen and long bone marrow contain the largest proportion of these substances. Various other experiments on animals indicate that the spleen is an important power in resisting infective processes.

3. The spleen as a member of the digestive system. All the blood of the spleen passes into the liver, carrying hemoglobin within the bodies of the wandering cells. The spleen, therefore, stands in an important relation to the liver. It is known, of course, that synchronous with digestion there is a slow expansion of the spleen, but what bearing this change may have upon the socalled digestive leucocytosis is not clear. It is stated that splenic extracts cause intestinal peristalsis. A further connection with the digestive sys-

---

*Read before the Medical Association of Central New York, October 19, 1922.

tem lies in the probability that the spleen takes part in purin metabolism.

4. The spleen as a part of the sympathicoendocrine system. The sympathetic nervous system provides a close network about the splenic artery and its branches and this in turn connects with the solar plexus and so with the adrenal glands. The vagus innervates the muscle fibres in the connective tissue. There is some experimental work also on the possible relationship between the spleen and the thyroid and the thymus glands but it is not conclusive.

Clinically the examination of the spleen concerns itself chiefly with changes in the size, shape and consistency. It is estimated that the spleen must be twice its normal size to be palpable. Enlargement of the spleen or splenomegaly occurs in a variety of conditions, grouped conveniently as follows: 1. Acute and chronic infections and venous stasis. 2. Leucemias. 3. Hodgkin's disease. 4. Splenic anemia or Banti's disease. 5. Gaucher's disease. 6. The socalled pseudoleucemias of infants or von Jaksch's disease. 7. Hemolytic states with jaundice.

It is proposed to discuss in this paper particularly certain anemic conditions in which splenic enlargement is a prominent feature—namely socalled splenic anemia, and, secondly, hemolytic icterus. A typical case of splenic anemia is illustrated briefly by this account.

CASE I.—No. 5220. A clerk, aged thirty-four, was seen in December, 1918. He stated that the preceding February he had had several attacks of severe vomiting of blood during which he nearly died. About a month before consultation, a similar attack occurred. Since that time he had had pain in the epigastrium usually after food but sometimes when the stomach was empty and then the pain was relieved by food for a time. He had had slight nausea and a little constipation. He had not noticed any blood in the stools. He recalled no previous severe diseases, had never taken alcohol to excess and none for two years, and had not smoked for three years. His father and mother died of cancer, one of the mouth, the other of the stomach.

Physical examination showed a slight undernutrition (ten to twelve pounds); pale mucous membranes; several suspected teeth, and a moderately enlarged spleen. Blood examination: Red blood cells, 3,744,000; hemoglobin, 42 per cent.; white blood cells, 2,400. The differential count showed 45 per cent. of large mononuclear cells. The test meal showed some obviously old blood. Dental examination showed extensive areas of rarefaction about nine teeth and two others were quite loose from pyorrhea. Further examinations indicated probable adhesions in the right upper quadrant of the abdomen but no further important diagnostic points were revealed.

It was considered that the patient was suffering from splenic anemia and it was determined to raise the level of the blood by transfusions and follow this by exploratory laparatomy with removal of the spleen if justified at operation. The infected teeth were to be extracted as soon as possible and the general physical condition of the patient brought up to its highest level.

This plan was followed out and the patient left the hospital after splenectomy in excellent condition with blood much improved though not quite up to normal. Letters several months later showed him well and able to attend to his work. Ten months later he reported gastric bleeding again but was able to go to work very shortly.

The essential features of this disease include a large, firm spleen, a marked secondary anemia, and a tendency to hemorrhage especially from the stomach. If the condition is allowed to persist for some time, changes of a cirrhotic nature occur in the liver, ascites develops and the patient finally dies.

The anemia is of the secondary type and of varying severity according to the grade and progress of the disease. There are spontaneous remissions also with periods of approximately normal blood. The color index is less than one. The red cells show moderate variations in size and the while cells are reduced in number. There is usually a relative lymphocytosis. There is some response to rest, food and blood tonics in general but it is by no means satisfactory. A large hemorrhage may, of course, make a sudden decided reduction in blood values.

Hemorrhages are sometimes very large when coming from the stomach. Less severe bleeding may take place as epistaxis or as hematuria or may occur into the skin, producing purpuric spots or areas. In advanced cases where cirrhotic changes in the liver are present the gastric hemorrhage may come from esophageal varices, but in the earlier stages it is more likely that there is rupture of the dilated vasa brevia into the stomach. Stasis or obstruction on the part of the spleen is certainly not the only element in the causation of hemorrhage since quite copious bleeding may take place after splenectomy though it is not common. Such bleeding is noted to have occurred in the case mentioned above. Gastric hemorrhages are often difficult to explain satisfactorily and it is sometimes said that they are of toxic origin especially in connection with lesions in the gallbladder, appendix, liver, and other organs. In any laparotomy which has splenectomy in view it is important that careful exploration should be made of the other abdominal organs. It is difficult to see the mechanism of this the ory of toxic origin unless we postulate erosion of the gastric mucosa. I have, however, in mind a case, showing a marked secondary anemia with melena, which was strongly suggestive of gastric cancer but which on exploratory laparotomy showed a normal stomach and the presence of gallstones.

The spleen in splenic anemia shows marked fibrosis, including thickening of the capsule and trabeculæ and changes of a fibrotic nature in the reticulum. Endophlebitis is also sometimes to be found. The spleen pulp itself is greatly increased in amount chiefly due to increased numbers of venules. Warthin believes that in many, if not in all, cases of splenic anemia the underlying condition is obstruction in the splenic and portal circulation most commonly due to thrombophlebitis. The action of the spleen normally may be likened to that of a filter, removing not only old red cells but also bacteria from the circulating blood and we must suppose the ordinary acute splenic tumor to be in part at least in connection with this function. If the splenomegaly is the result of the isolation of malarial organisms or of tubercle bacilli or the spirochetæ of syphilis, or other organisms, then we have a specific disease and we regard the enlargement of the spleen as merely one of the body's protective measures. There must be, however, many similar splenic reactions against various bacteria or toxins. If this be pronounced, of fairly long standing and accompanied by anemia of marked grade, we group the cases as splenic anemia or Benti's disease. This at least is the present status of the matter. This theory practically infers that the anemia is a secondary matter and that the splenic enlargement is the primary thing. We could, of course, refer the anemia to the hemorrhages except for the fact that they are not constant and, in fact, are absent in some cases showing very low red counts. The red cells in splenic anemia do not show an increased fragility. W. J. Mayo leans to the opinion that a fibrotic spleen destroys more red cells and that in the absence of any special stimulation of the bone marrow anemia must result. He suggests, too, that the disease changes may bring about reduction of the pigment production and thus actually reduce the hemoglobin balance.

The extraordinary thing, however, is that removal of the spleen seems to remove the bar to blood production for there is rapid and permanent return to an approximate normal count. No other form of treatment has been found to bring about this result. For this reason alone it is justified but there are added and important advantages in thus not only ridding the patient of the weight and discomfort of the enlarged organ but also in avoiding certain unhappy complications such as traumatism, rupture, and other conditions.

In passing, it may be well to refer to certain cases of splenomegaly with lues in which the patients seem unusually resistant to any antiluetic treatment. Mayo has seen a number of such instances which responded readily after splenectomy, suggesting that the spleens were the hiding places of many spirochete. The case reported below, which was recently under observation, suggests this condition.

Case II.—No. 8111, a man of thirty-four, who complained of general weakness and indigestion. He stated that about one and a half years ago he became jaundiced. An exploratory laparotomy was done but he was told that nothing was found beyond thick and obstructive bile. Biliary drainage by duodenal tube was done on several occasions and gradually the jaundice cleared. At about the time of the operation the blood Wassermann was found to be positive. He then took salvarsan treatment and followed it with mercury. The spinal fluid was said to be negative. About two months ago the blood was found to be still positive.

Full and careful examinations in this case showed emaciation, aortic and mitral insufficiency, a spleen reaching practically to the umbilicus and a marked secondary anemia with low white count: the red cells 2,408,000, the hemoglobin 44 per cent., and the white cells 3,750. There were constantly a few red blood cells found in the urine. The blood Wassermann reaction was strongly positive. There was no history of hematemesis but there had been some blood coming from the nose during the summer. The case probably represented a splenic anemia with lues in addition though it is quite possible that the lues was the primary factor.

In this instance the poor general condition made one advise a preliminary upbuilding with antiluetic treatment but in all probability splenectomy will have to be done before any lasting improvement can be expected.

We may then formulate a theory that splenic anemia is the result of a chronic infection or toxemia bringing about fibrotic changes in the spleen, which in turn acts to destroy increased numbers of red blood cells and may, in addition, be the means of disturbing the hemoglobin balance of the body. Severe hemorrhages are usually the result of engorgement of certain bloodvessels and are usually of mechanical origin though toxic forces sometimes have been invoked to explain certain hemorrhages which in some instances may be from mucous membrane erosions. A continuation of the condition brings about further lesions in the liver of a cirrhotic nature, more nearly corresponding to the description of Banti's disease with its later development of ascites and a general downward course. Splenectomy is the only effectual treatment.

Another type of anemia with splenomegaly and certain peculiar added features is exemplified by the following case:

Case III.—No. 7240 was a boy of nine years who was examined in April, 1921. He is stated to have had influenza about two years ago at which time he was sick for two months. Since then he tired very easily. Five or six weeks previously he was noted to be anemic and his family physician on examining him found an enlarged spleen. The family history was most interesting. The patient's mother died about a year ago of what was said to be influenza. Many years previously Sir William Osler had examined her and found an enlarged spleen. The patient's maternal grandmother accompanied him and was seen to be slightly but definitely jaundiced. She stated that she had gallstones, gave the information about her daughter's spleen and added that Sir William Osler also found an enlarged spleen in her case.

The boy himself was well nourished but showed a definite yellowness of the skin and scleræ. There was a litle general glandular enlargement. The spleen reached about to the level of the umbilicus and was very firm.

On examination of the blood the red cells were found to number 3,472,000; hemoglobin, 60 per cent.; white blood cells, 15,000. The red cells themselves showed marked variation in size, shape and hemoglobin content. Many of the cells showed marked polychromasia and there were many huge cells; four normoblasts and one intermediate were seen in a single smear. Platelets were normal. There was nothing remarkable about the white blood formula. Blood Wassermann reaction was negative. Other examinations of the blood showed a definite increase in the fragility of the red blood cells. There was marked increase in the number of reticulated red blood cells seen on vital staining. Two tests of urine gave markedly positive reaction for urobilin, otherwise the urine was normal. The case was considered to be one of familial splenomegalic anemia with slight jaundice and increased fragility of the red blood cells, in other words, a congenital hemolytic icterus.

The general condition was explained to the family with the advice to treat the anemia by rest, iron, and other treatment, for a time. The bearing of splenectomy on the case was explained but since the boy seemed fairly well it was decided to postpone this for a time at least. Letters six months or so later reported that the boy was in good condition and attending school.

Here we see then marked secondary anemia, splenomegaly and acholuric jaundice, that is, icteric discoloration of the skin but with absence of clay colored stools and dark urine—a syndrome corresponding to hemolytic jaundice. The most important essential for the production of the disease seems to be increased fragility of the red blood cells.

Attention was called to slight, chronic, congenital jaundice with splenomegaly in 1890 by Claude Wilson. Within a few years an acquired type was also differentiated. The case quoted shows a remarkable familial trend since both mother and grandmother had large spleens and the grandmother was noticed to be jaundiced and to have a history of gallstones. This family tendency is a frequently recognized characteristic of the congenital cases. The findings in the acquired type do not differ materially from the congenital form but the acquired types are likely to be much more severe and of more serious outlook. Indeed the congenital form may cause little or no disturbance and the patient may live to a very great age.

These facts are, of course, of the greatest importance in considering the advisability of splenectomy. It is interesting to note that the presence of gallstones is a frequent finding in cases of hemolytic icterus coming to operation.

Confusion is still further introduced by the occurrence of socalled crisis during which there is malaise, fever, sensitiveness of the spleen with increase in its size, deepened jaundice and sometimes an enlarged liver with tenderness in the epigastrium. There is found an acute anemia during these periods and it is supposed that a sudden unusual hemolytic activity is responsible for the whole picture unless in those cases where an actual biliary obstruction is indicated by acholic stools and bile in the urine. These cases of hemolytic icterus show a secondary anemia which, particularly during the crises, exhibits evidence of regeneration including nucleated red cells, etc. The red cells should always be tested with hypotonic salt solution since it has been clearly shown that in this disease there is definitely decreased resistance. In the case of the boy already quoted the hemolytic limit was .55 per cent. sodium chloride while the normal control was .4 per cent. sodium chloride. Vital staining should also be resorted to in order to determine the number of reticulated red cells since this gives an indication of the response of the bone marrow. They are probably youthful red cells hurriedly sent out by the bone-marrow. A large number of such forms show an actively functioning marrow. In aplastic cases they may be nearly absent. This particular case showed thirteen per cent. of reticulated cells as against one per cent. in a normal control.

The jaundice is interesting in several particulars. It is usually not very intense though subject to variations. There is no itching of the skin. The stools contain bile and the urine contains no bile (unless, of course, complicated by actual obstruction of the bile ducts) but does contain urobilin. These facts, of course, merely indicate the mildness of the jaundice for we know that bile pigments are held in the blood up to a certain point which we may call the threshhold. If concentration proceeds beyond that point jaundice appears.

Even if we accept the theory that increased hemolysis leading to greater concentration of bile pigment in the blood results in jaundice and increased urobilin in the urine because of the insufficiency of the hepatic cells, we are still faced by the fact that splenectomy relieves the condition and so we reach the conclusion that the spleen plays perhaps the most important rôle in this condition. The two principal theories of the causation of the disease have been: 1, an increased fragility of the red cells, and, 2, increased hemolysis induced by the spleen. We can not choose between these two since removal of the spleen is usually attended by complete relief including decreased fragility of the red cells but in several recorded cases symptomatic relief was complete but the cell fragility was unchanged. Examination of such spleens after removal shows only a congested pulp with no specific changes.

Splenic anemia and hemolytic jaundice present certain similar manifestations and this is particularly true as regards relief of splenectomy. It is pretty certainly determined that after splenectomy in general the red cells of the body show increased resistance to hypotonic salt solution and to hemolytic poisons. Unless undertaken very late in these two conditions or in the presence of serious complications this proceeding does not present undue hazards. The Mayo Clinic reports give a mortality of 12.3 per cent in seventy-three splenectomies for splenic anemia and a mortality of 3.2 per cent. in thirty-two cases of hemolytic jaundice. One of our own patients returned for examination nine years after splenectomy for splenic anemia with severe hemorrhages. He had led an active life but returned because he had observed two tarry looking stools. All examinations were negative however.

CONCLUSION.

We must think of the spleen in general as a mass of cells having in general the attributes of lymphoid tissue and variously related to other organs in the body. In its absence other lymphoid tissue may act somewhat vicariously for it. Phagocytic cells in the spleen undoubtedly break down red cells and transport the altered hemoglobin to the liver. There is as yet no proof that the spleen produces a true internal secretion. The results of splenectomy in splenic anemia and in hemolytic jaundice show that the spleen plays at least a most important rôle in the pathogenesis of these two conditions.

The Dark Age in Medicine

*A Projected Retrospect**

By EDWARD HUNTINGTON WILLIAMS, M.D., and
ERNEST BRYANT HOAG, M.D.
Los Angeles, Calif.

We have chosen for our subject on this occasion a brief discussion of the conditions prevailing in our profession just one hundred years ago—that is, in the 1920 period. This period of the early twentieth century, as you all know, has been aptly termed "The Dark Age in Medicine." Perhaps it would be more appropriate, however, to call it the Dark Age *for* Medicine, or, at least, for medical men, since it was not the ignorance of the physicians at that time that earned the period the sobriquet, but rather the ignorance of the general population about medical matters. That the physicians of that period seem so utterly submerged was not really due to their lack of accomplishment, for their accomplishments were amazing; but rather it was the failure of the majority of persons outside the profession to understand and appreciate what regular medicine had done and was doing—the majority that guided and controlled the destinies of our country at that time.

There was a reason for this, and a very good one, namely, the intelligence of the average American of that time. Far from being the almost superman he had thought himself, the investigations of the great war had led to the astonishing discovery that twenty-five per cent. of all Americans were illiterate, while the average intelligence was that of a fourteen year old child! It was one of the most amazing and shocking discoveries in American history. Yet how could it be otherwise? This great El Dorado of the West with open doors through which Europe had been pouring its scum for a century—what other effect than degenerating pollution could result?

This result showed in the literature, music, art, and amusements of the time. The average American's literature at that period was almost exclusively the ochre tinted newspapers devoted largely to crime, socalled politics, and other forms of scandal; his music was a rhythmic combination of discordant sounds called jazz; his art was the daily pen sketch in the funny sheets, simplified to line drawings to meet the prevailing intelligence level; and his amusements were those requiring speed rather than culture. All this, of course, the natural result of an average fourteen year old intelligence.

But do not imagine that this puerile intelligence level applied to the members of our profession. On the contrary, the wise old physicians of that period had been steadily lifting their membership intelligence level so that no fourteen year old adult could join the select fraternity. Yet, since the country as a whole was governed and judged by this childish standard, one may readily understand why it was that the great science of medicine was so submerged and popularly opposed at that time. It was merely an inability to comprehend—and hence to condemn. Naturally, there could be no other result.

Please bear this fourteen year intelligence level in mind. It will help to explain some of the seeming obliquities of that particular Dark Age.

The fact that the physicians appreciated their position at that time, and that they retained a sense of humor, is shown in the preface to a little book written by a physician of that period. The book is called *How to Practice Medicine*. And in the preface the author says: "This book is for physicians only—everyone else, of course, knows all about this subject." It is probable that some of the better class of laymen appreciated this bit of sarcasm as well as the physicians. Still, the status of the physicians of that time contrasted strikingly with that of physicians in the preceding century. Thus, six honored physicians were among the signers of the Declaration of Independence made during the Revolutionary War. Yet, in the great war of this Dark Age period we find no popular adulation of even one medical man—no popular acclaim of the profession whose victory over war injuries and war diseases was far more decisive than any victory of arms.

This suggests that in the year 1920 there were many persons who practised the healing art other than those belonging to the regular medical profession. There were, indeed; and, moreover, these dealers were permitted to practise their art unmolested by the authorities and even actually encouraged by them. There were, for example, types who cherished the peculiar delusion that there was no such thing as disease or death—or almost anything else. In the year of 1920 this form of superstitious jugglery was extremely popular. The cult had been originated by a charming old gentlewoman of Boston who taught that disease was nonexistent, and from her teachings acquired great fame—also great earthly emolument. After which she died of disease.

This Dark Age was a period of superstition in which muscle and politics were exploited at the expense of brains. At that time government of the politician, by the politician, and for the politician had not yet perished from the land; bricklayers received higher pay than many college presidents; and locomotive engineers frequently received larger pay checks than did the Governor of the State in which they operated their trains.

As for superstition, there appears to have been a striking similarity between the people of America and those of the much despised Chinese Kingdom of that period. For example, the Chinaman whittled images out of wood which he set up as gods to act as mediums for communication with the Divinity. The Chinaman's method was somewhat crude, since he had no means of checking up or recording the messages received. The American's method was better—more exact. He whittled his god out of wood, to be sure, but instead of making the image of a man he shaped it into the form of a small three legged table which he called a ouija board. This wonderful board, when properly manipulated by deft fingers and active imagination, would spell out perfectly definite answers to questions and transmit written messages from almost any kindly disposed and unoccupied spirit living in the world beyond.

---

*From an address delivered in the year 2020 A.D. before the International Congress of Physicians at its annual meeting.

The advantage of this type of idol over the Chinese one is obvious. The Chinaman must necessarily guess at the messages he received, while the American would get his message written down in perfectly plain English. And thus it became one of the popular indoor sports of the period to hold long and arduous communications with the shades of the other world. So it followed that instead of spending his evenings in meditation, or in reading the printed earthly messages of the departed great, such as Socrates, or Baron Munchausen, or Mother Eddy, the American simply took to his ouija board and talked to these people direct. It must have been much more gratifying to get in direct communication with any shade one cared to, than to read his earthly platitudes. But one cannot escape the feeling that it may have been a trifle hard on the shades, particularly ,the popular ones, on rainy evenings when everyone was at home and the ouija boards working on full time.

That this had a direct bearing one the practice of medicine, one may readily understand, for when one could receive direct communications from any of the great departed physicians he chose, why waste time and jeopardize one's health by calling in the local physician who was necessarily young and inexperienced by comparison. Better by far to have your attack of indigestion treated directly by Hippocrates, Galen, John Hunter, or Osler, thus obtaining the very best advice for the least possible monetary remuneration. Such things make strong appeal to the fourteen year intellect.

One should remember, of course, that the practice of medicine at this time was a strictly localized affair, and the doctor simply a local agent, so to speak. Merely because a man was a great physician licensed to practice in one State it did not follow that he was accepted as a physician in an adjacent State perhaps only a few blocks away. Thus an eminent physician in Massachusetts was no physician at all in Connecticut, for example,—was a law breaker if he prescribed a dose of castor oil that could legally be dispensed by a local veterinary or midwife. Yet, obviously, if a dose of castor oil prescribed by Dr. Wise in the Bay State was good for infantile colic in Massachusetts, the same prescription written by the same doctor for the same condition in Connecticut should have been equally good. But such was not the case, at least legally speaking, in the year 1920.

One must bear in mind also that in the submerged period of which we are speaking, physicians were only one group in a large and diversified assortment of people who practised the healing art. Indeed, after running over the list of persons other than the regular physicians who were permitted to treat diseases, one is inclined to place the physicians of this Dark Age somewhere in the "also ran" class—a sort of glorified peace officer's assistant, particularly useful to undertakers for signing death certificates.

For example, there was a large and influential body of healers who based their treatment of most human ailments on the theory that the bones of the spinal column are forever slipping slightly out of place thus causing all manner of dire physical catastrophes. And it was the function of this group of socalled physicians to alleviate these ailments by deftly pushing the misplaced vertebræ back into alignment, often with a simultaneous cracking of the knuckles which was tremendously helpful in a psychotherapeutic way.

Now it seems to us today that any intelligent person capable of ordinary reasoning power would have some doubt about this wabbly, slippy condition of the human spinal column. Even at that period persons must have observed the lower animals and have noticed that the spinal columns of such animals were able to withstand all manner of strains and abuses, and that even infants constantly subjected their backbones to the worst kind of maltreatment. And they should have been able to reason that the adult human spinal column did not differ very materially from the corresponding organs of other animals or of the infant, that it was, indeed, the one anatomical organ that really tended to "stay put" as nature originally constructed it. Moreover, it was common knowledge at that time that the real scientists were never able to detect these minute slippings of the spinal vertebræ. But here was where the fourteen year old intelligence came in: these grownup children would believe almost anything that was told them. And so these spine adjusting physicians attained great popularity with the trusting but guileless general public.

Which leads one to draw the mental picture of a community in which the idea of the stability of the spinal column was comparable to that of the chocolate eclair, a popular, squashy sort of dessert of that period. One can picture the apprehensive members of such a community going about with baited breaths, holding themselves in rigid suspense lest some sudden exertion on their part should throw their degenerate vertebræ out of alignment. Or see them rushing off to the spine adjusters to have their vertebræ lined up after the catastrophe had happened. It is difficult for us to believe, at this time, that such things really happened among presumably intelligent people in the dark period of 1920. Yet there is no gainsaying the fact—the records speak for themselves.

It is interesting to note that this form of treating diseases never found much favor among the Dark Age veterinaries or their clients. Perhaps the general attitude toward the subject is tersely enough expressed by a rural legislator of that time when approached on the subject of possible veterinary osteopathy legislation. "No, sir," he said, "we don't allow no fool experiments on our dumb critters—they're too valuable."

But these spine adjusters of this particular school were not permitted to pursue their vertebræ treatments without rivalry. They had hardly reached the pinnacle of popularity when another body of spine adjusters appeared as rivals—socalled doctors who might aptly be termed ultraspine adjusters.

These persons termed themselves chiropractors and focused their energies solely upon the spinal column, whereas their predecessors had now broadened their views sufficiently to admit that certain diseases—such as lues, the hives, or ectopic gestation—were not entirely due to some slight vertebræ displacement. So that presently the chiropractor was manipulating the spine of patients in every State, and was almost everywhere recognized by law as equally competent to care for ailing humanity as the regular physicians who had devoted years of study to scientific subjects.

It is difficult for us at the present time to understand just what chiropractic was; but here is the accepted definition given by D. D. Palmer, the creator of this strange mental obliquity. "Chiropractic," he says, "is a name given to the study and application of a universal philosophy of biology, theology, theosophy, health, disease, death, the science of the cause of disease and art of permitting the restoration of the triune relationship between all attributes necessary to normal composite forms; to harmonious quantities and equalities by placing in juxtaposition the abnormal concrete positions of definite mechanical portions with each other, by hand; thus correcting all subluxations of the spine, atlas to coccyx inclusive, for the purpose of permitting the recreation of all normal cyclic currents, through nerves, that were formerly not permitted to be transmitted, through impingement, but have now assumed their normal size and capacity for conduction as they emanate through intervertebral foramina—the expression of which were formerly excessive or partially lacking named disease. (To replace the full quota of positive with an equivalent negative; permitting the reconveyance of the intelligent immaterially into the mechanical corporeal.)"

From all of which one is able to see at a glance that chiropractic was a very serious as well as a wholly incomprehensible thing, carefully chambered to fit exactly into fourteen year calibred intellects. However, it has been suggested that through some printer's error the above definition is misquoted—is, indeed, an old English court form of conveying the power of attorney or some other similar legal complexity. But such is not the case. It is "Doctor" Palmer's own definition; and it is to be hoped, even though doubted, that he, at least, thought he knew what he thought he was trying to convey, or failing to convey, in his verbal meanderings.

Now, should anyone at the present time doubt that these chiropractics were taken seriously at that period, witness the following passage quoted verbatim from a newspaper printed in the year 1921 describing the treatment of a certain fair chiropractic operator who seems to have done something not subscribed to in the code. In large type we read as follows:

> "PARADE TO TAKE GIRL DOCTOR TO JAIL.
>
> Alice Huhn, Twenty-One, Chiropractic, to Serve Term for Practising Without License.
>
> "A parade of more than sixty automobiles will escort a girl to jail at Santa Ana tonight.
>
> "The girl is Alice Huhn, twenty-one, Orange County chiropractic doctor, who will begin serving a sentence of sixty days in the Orange County Jail for practising without a license.
>
> "In the same cell where Bebe Daniels, film star, was incarcerated for ten days, victim of a court sentence for speeding on an Orange County highway, Miss Huhn will remain for sixty days.
>
> "Chiropractors from all sections of Southern California will assemble in automobiles tonight in Anaheim, where an 'honor parade' for Miss Huhn. The parade will begin at 7:30 o'clock at the office of Dr. Huhn in Anaheim, and will proceed through that city and Santa Ana to the jail, decorated with banners and traveling to the strains of a brass band.
>
> "Anaheim friends of the girl and other members of the chiropractic profession are planning to bedeck the cell in the same grandeur and luxury as when Bebe Daniels was an inmate. They will keep her cell fresh with flowers during the period of the sentence.
>
> "Doctor Alice Huhn was born in Anaheim and has lived in that city ever since. She is a Sunday School teacher in one of the Anaheim churches."

Apparently there was a premium on crime in those days. And, considering this ovation paid to a lawbreaker because of her lawbreaking, one is forced to the conclusion that there certainly was considerable incentive for becoming one of these socalled chiropractic thrusters. I do not find any record of a regular physician lawbreaker of that time being paraded to flower lined cells because of his lawbreaking, although of course criminal worship was then quite a popular form of devotion. Still, one must not judge too harshly. There are limitations to the reasoning powers of a fourteen year intelligent level.

And one must always bear in mind also the standards by which popular heroes were measured at that time. It was the age when emotion rather than calm intellect seemed to dominate. And we know the truth of the assertion of Dr. Dana, a very great physician of that time, to the effect that "when emotion dominates, civilization halts or disappears." And as an example of what emotion may do in the field of hero worship one has but to recall a notorious criminal case of that period in which the discarded husband of an alleged murderess became "the man in a million," and was featured by the movies, and invited to speak from pupits. From our present point of view this seems a queer bid for fame—a thing to entitle one to be termed "one man in a million." But possibly this was a subtle bit of irony: being exceptionally unlike the usual run of mortals does not necessarily imply superiority.

The law, which has always been notoriously hidebound, seems to have lived up to its traditions during the Dark Age period. The one redeeming quality of the lawmakers seems to have been a subtle and abiding sense of humor which radiated all through their grim work. Thus, one finds the perennial pleasantry obtruding itself everywhere to the effect that, "a man is considered innocent until proved guilty beyond a reasonable doubt." Apparently this was a standard legal joke at the time.

But meanwhile, any person suspected of a crime was, first of all, locked in jail, on the assumption, we suppose, that being still innocent he might otherwise become contaminated if allowed his freedom. But, lest the monotony of confinement prove irksome to so innocent a person, things were sometimes enlivened by certain third degree proceedings which abounded in humor—at least from the legal point of view. Of course any such inquisition methods worked upon a freeborn and innocent American citizen was entirely illegal. And, let it be said to the credit of the legal fraternity of that Dark Age, that persons guilty of perpetrating these inquisitional methods were sometimes admonished, or even warned by the courts.

But these little humorous touches in the legal proceedings before the actual trial were entirely offset by the sinister pageant of the trial itself. This trial was presided over by a judge, part of whose duty was to prevent lawlessness among the lawyers; and a bailiff, who exercised the same restraint over the audience. There were also twelve or thirteen jurors who were chosen largely for their lack of knowledge or opinion. If they had an opinion they couldn't be jurors. Thirteen was considered an unlucky number at that time.

The trial itself was divided into three parts. In the first part certain witnesses who were sworn to tell "the truth, the whole truth, and nothing but the truth," were allowed to tell such portions of the truth about the accused person's guilt or innocence as the opposing lawyers and the legal technicalities permitted. You see, the whole truth part was a little legal pleasantry, also. Meanwhile, in some of the older States, such as Massachusetts, the prisoner sat in the court room in an iron cage built like a miniature prison. At the present time we are quite unable to understand the object of this cage unless it was for the twofold purpose of emphasizing the legal pleasantry about the presumption of innocence. In our own time it has been suggested that this human bird cage did not enhance this presumption.

The second, and more pleasant stage of the trial, followed immediately after the testimony by the witnesses. The object of this stage of the trial was to give the attorneys a chance to show their skill as orators. Theoretically, you understand, the jury was supposed to decide upon the man's guilt or innocence by evidence presented. But in this second phase of the trial it was the function of the attorneys on each side to make the jury discredit anything said on the witness stand for or against the prisoner according to the particular side by which the attorney was employed. And just as a means of emphasizing the legal pleasantry about the accused person being innocent, the prosecuting attorney was given the place as valedictorian, so that his flights of oratory proclaiming the prisoner's guilt were the last things still ringing in the jurors' ears when they retired for deliberation, except to cut and dried platitudes read to them as a matter of form by the presiding judge.

Looking back at this particular proceeding from the lapse of a century one can appreciate the subtilty of the law's humor in considering the prisoner innocent until proved guilty beyond a reasonable doubt. Undoubtedly it seems more humorous to us now than it did to the prisoner at that time. But the results were not nearly so bad as one might suppose; for the third stage of the trial was yet to come. This was the socalled deliberation of the jurors.

Theoretically, you understand, each juror was supposed to have formed his opinion about the innocence or guilt of the prisoner from the statement of the witnesses and the bursts of legal oratory that had been forced upon him. And one would suppose very naturally, since he would hear no more of these things after being locked in the jury room, that his opinion expressed in his first vote would be his real opinion based on the evidence, and the only one that would be considered. But such was not the case at all. In point of fact, the first vote was rarely unanimous. And that was where the juror orator come into his own.

Perhaps, as the result of the first ballot, a majority of the jurors held to one opinion about the prisoner's guilt or innocence, while the remainder expressed precisely opposite views—this, you understand, based upon the evidence. Now it was up to the members of the jury to harmonize these conflicting opinions. And that was where convincing oratory came into play. Locked in a closed room from which none could escape the contesting orators representing one side or the other, tilted and jousted with each other, using every means at their command save actual physical violence (which, we believe, was not permitted in most cases) until at last one side prevailed over the other in the matter of convincing oratory and the jury was so harmonized that it voted unanimously.

In cases where there was one dominating orator on the jury a unanimous verdict was often easily attained. But when it happened that there were two equally matched lingual gladiators, or gladiatoresses, in the closed arena, the result was often indecisive, and the jury was said to be "hung," in the vernacular. When the jury was hung the prisoner wasn't.

All this strikes one as very childish. But we should remember that laws in the medical Dark Age were a heritage from the original Dark Age handed down directly and with little change. For law is essentially unprogressive.

This peculiar childishness in legal matters was shown in another way. Thus, the standard test of an accused person's mental responsibility the country over in this Dark Age, was whether or not he "knew right from wrong." In the case of serious crimes when the prisoner passed the "right from wrong" test successfully, he was hanged or electrocuted or otherwise dispensed with. If he failed in this test he was placed in a hospital or turned loose to try it again.

This right from wrong test should not be confused with the ordeal, or primitive sink or swim test, which really belongs to a much earlier period. According to this test the accused person was innocent if he sank and guilty if he swam when thrown into the water. And although this test was described minutely by Mark Twain, who was a contemporary of about that period, it should be understood as a legal measure in the Dark Age period. The law was, after all, somewhat progressive, you see.

As would be expected at this rather low stage of social development credulity was the dominant note. It appears that our worthy ancestors would believe almost anything, particularly if they saw it in print in the newspapers and if it pertained to the supernatural. Not all the members of our profession were exempt. For example, the great English physician writer, Dr. Conan Doyle, apparently overwrought by his experiences in the great war that had just passed, proclaimed some very curious conditions in the spirit world. As quoted from the contemporary newspapers of that time he is said to have discovered certain conditions existing in the hereafter, gave popular lectures on the subject, and upset many preconceived ideas of happiness in the Great Beyond by declaring that, "there are marriages in the spirit world, but no births." And, curiously enough, there were thousands of good Americans who accepted this idea of happiness, despite the fact it conflicted with the views of the great Roosevelt, who had only recently declared that marriages without births were likely to be doleful affairs, preeminently unhappy.

At this time, every person in America being "born free and equal" according to the great constitution, seemed to accept this untruthful impossibility as a fact. As a consequence, each person considered himself just as competent as any other person to pass upon any subject whatsoever. And as we would expect, there was some very childish legislation about medical things of which the general public had very inadequate knowledge, but which, with the willingness to rush in where angels might have hesitated, they passed without question.

Thus, there was the legislation about the use of opium and its products. At that time these products were the most useful remedies and the only ones that would control pain in many afflictions, besides being invaluable for other conditions. Yet, by a curious pieces of legislation, and despite the fact that doctors were considered the only persons competent to administer these remedies or decide when they should be administered, the control of the whole situation was placed in the hands of laymen. Some of the legislation that resulted was just what might be expected under the circumstances.

For example, since many of these remedies were used hypodermically, it was legally forbidden to sell, buy, or have in one's possession hypodermic needles or syringes except by special permission. And yet there were a host of remedies at that time could only be administered hypodermically, and that contained no opium products whatever. But since a small percentage of persons used hypodermic needles for administering morphine and heroine, everybody was forbidden the possession of hypodermic needles in the hope of preventing this inconsequential minority from taking drugs illicitly.

To be sure, the hypodermic needle was not necessary for the administration of these drugs and it was absolutely necessary for the administering of many other useful substances. So that the law which attempted to control the illicit traffic by forbidding the sale of one means of administering the drug was just about on a par with a law that would attempt to bring about starvation in a besieged city by forbidding the inhabitants to use knives or forks. It seems almost superfluous to say that this law did not decrease the amount of opiates used by the addicts. Meantime, however, it did interfere with the health and comfort of legitimate sufferers; and the whole legislative aspect was detrimental to the members of our profession. Criminal addicts, however, encountered no particular difficulties, as narcotics easily found their way into jails and pentitentiaries. Indeed, it has been shown that this sort of traffic was surreptitiously encouraged by those in authority in some institutions who found discipline was thus rendered a much easier problem for them.

The whole procedure of drug addiction control, from the legislators at Washington to the Federal courts and detectives and the arresting officers, concerned itself only with the legal aspects of the question. And the fact that drug addiction was almost exclusively a medical problem, seems to have been suspected by no one but certain physicians who were not permitted to concern themselves with the matter along scientific lines.

Moreover, that treating addicts as criminals appeared to increase criminality, seems not to have dawned upon the inner consciousness of the lawmakers and the law enforcers. Which is easily understood when we reflect that in the 1920 period criminal law was practised very largely on the procedures laid down in the eighteenth century. Law was indeed several centuries behind its own Dark Age.

One could continue almost indefinitely recounting the curiously childish things that concerned medicine either directly or indirectly which were constantly perpetrated in this Dark Age, but space forbids more than a passing reference to some of the most notorious. For example, some of the more markedly incompetents of that period who were, or had been, office holders by grace of the ballot, tried to discard Darwin's theory of evolution—the great foundation stone of all modern science and progress. Not only attempted to discredit it because mentally incapable of comprehending it, but attempted to forbid the teaching of evolution in public schools.

On one occasion a certain William J. Bryan, sometimes called the "Commoner" (a tersely descriptive term of that period) speaking in the Hippodrome in New York is quoted as saying: "They tell me that you can read the history of the earth in the records of the geological ages written in the rocks. As for me, *I* cling to The Rock of Ages!!" The audience "raised the roof" with applause—fourteen year old reasoning as pabulum for fourteen year old intellects.

It was the age when the reformer was still allowed at large and uncoralled—queer pathological types of both sexes, not always, however, clearly differentiated—who did not wish anybody to do anything that they did not enjoy themselves. Their idea seems to have been to transform all red blooded men into human cabbages oblivious to the fact that all the progress in the world has been produced by this same red blood. But of course they did not know this—did not, indeed, know many things that even modern boys of today know.

Yet these queer, mournful minded creatures with their obvious endocrine unbalance, had a tremendous following, and as would be expected, they were usually stoutly lined up against scientific medicine. But why not? Since any other mental attitude would have been a reflection upon the very name of science, in this curiously retrogressive period of our country's development when there was more crime, more degeneracy, and more general ignorance than recorded in several centuries—when the mind of the average citizen was the mind of a half grown boy, with all its foolish impetuousities, but without the saving grace of actual youth itself.

Editorial Articles

THE TREATMENT OF DIABETES

If the introduction of insulin has not altogether revolutionized the treatment of diabetes it has at least established a certain amount of control over the disease. An editorial and an address (*Canadian Practitioner,* March, last) have been published recently on the subject which place the part played by insulin in treatment in the proper light. The methods for extracting the substance secreted by the islands of Langerhans and the clinical trials on diabetic patients are described and then the value of the treatment is discussed. It is pointed out that insulin is not a cure for diabetes but seems to occupy a similar position in the treatment of diabetes that thyroxin occupies in hypothyroidism. In both cases there is a continued need for the missing secretion. There is no evidence at present to lead one to believe that destroyed islands of Langerhans can be regenerated, though there is ground for hoping that earlier pathological changes may be repaired. At the same time, it may be assumed that such tissue as is only functionally damaged may recover a large part or all of its capacity, because of the rest which it enjoys while the secretion is supplied artificially. The Allen treatment attains the same end in a different way. That this actually occurs in certain cases after the use of insulin evidence is already at hand to show. The writer of the editorial in the Toronto medical journal places his finger on the true therapeutic triumph of insulin so far, that is, its dramatic action in those cases where the patient is either actually in coma or hovering on the brink of that condition.

It may also be mentioned that insulin is of much value in its capacity to render a diabetic person in a safe state to be operated upon if necessary. The address commented on was given by Dr. Hugh Maclean at the Congress of Public Health held at Scarborough, England, on May 18, 1923, and published in the *Lancet,* May 26, 1923. This address entered fully into the subject but the statement on the value of insulin is so good that it may be quoted. Dr. Maclean said that he has now treated nearly twenty patients suffering from severe diabetes and in every case with entirely satisfactory results. No untoward symptoms of any kind occurred in any case. Patients who were almost moribund a few months ago are now back at work, and three subjects who were first seen while in a state of diabetic coma are now quite fit.

There can, therefore, be no question of the great value of the remedy. Its principal drawbacks are that it does not cure, but merely alleviates the condition while it is being given, and the fact that it has to be administered hypodermically. No doubt, in comparatively recent acute cases, its use may occasionally result in a return of tolerance, just as was sometimes the case with dietetic treatment, and Dr. Maclean has seen one case of this kind, but he goes on to point out that it is impossible to say whether the same result could not have been achieved by diet. Since, however, this boy was actually in coma when first seen, insulin was naturally used. He is now taking quite a large diet with one single small dose of five units of insulin a day, and is apparently normal with a resting blood sugar of about 0.1 per cent. and no glycosuria or ketosis. In long established disease he has seen no signs of increase of tolerance after insulin, and doubted whether in such cases much is to be hoped for in this direction.

What exactly the future of insulin will be it is impossible to say. That its advent has provided the greatest therapeutic measure in the treatment of diabetes is certain. Dr. Maclean thinks that probably many patients will ultimately learn to inject the drug themselves, or make some arrangement for a friend to do this for them. Insulin is almost exactly on the same footing as thyroid extract in the treatment of myxedema, with the disadvantage that insulin cannot be taken by the mouth. That it is capable of eliminating the symptoms of diabetes and restoring strength and energy to the unfortunate sufferer is now definitely established.

In short, insulin as it is now prepared is of considerable value in the treatment of diabetes and its potentialities cannot be gauged. The production is more satisfactory than was anticipated and it seems that the fear that it will not be forthcoming in sufficient quantities is not warranted. The standardization of the extract as to its strength is essential for its safe use, but no doubt this difficulty will be overcome, as will also the production of an extract whose action is spread over a longer period. Of course, the oral administration of insulin would greatly simplify treatment and while there are many difficulties in the way of producing an extract with the therapeutic virtues of insulin which may be given by the mouth these difficulties should not be insuperable. In fact, a pancreatic preparation to be given by the mouth was described by Dr. R. L. Mackenzie Wallis in the *Lancet,* April 14, 1923, and in the May 26th issue of the same journal Dr. Martin O. Raven records a case under his care in which satisfactory results followed the use of this preparation. Dr.

Banting and Dr. Best and their coworkers in Toronto are endeavoring to solve the outstanding problems in connection with insulin and it is likely that it will not be long before, at any rate, some of the difficulties will be mastered.

Before leaving the subject of the treatment of diabetes by insulin, it should be said that at present treatment with it requires knowledge and care on the part of the medical attendant. He must first convince himself that the case is one of true diabetes mellitus and then exercise great discretion. The rules for treatment by insulin laid down by Dr. Maclean are to be commended to the notice of medical men and especially that the principle of correlating diet to insulin doses must always be observed.

There should be no insuperable difficulties in the way of preparing pancreatic preparations of benefit to sufferers from diabetes which can be given by the mouth. Even if insulin cannot be so prepared and even if such preparations do not possess the potency of insulin, so long as they relieve to some extent, they will be useful. It is asserted that preparations of this nature are already to be obtained and from the account of Dr. Mackenzie Wallis's preparation this sounds as if it might be true. It is obvious that insulin as now administered is beyond the reach of many sufferers from diabetes. Indeed, now it is only the treatment of the few. The success of insulin has revealed in a striking manner the vast possibilities of scientific gland therapy.

HIGH AND LOW ENEMATA

With the desire of learning exactly what nurses of the present day are taught with regard to the administration of high and low enemata, S. W. Ellsworth and F. E. Wheatley (*Boston Medical and Surgical Journal,* April 12, 1923) sent letters of inquiry to the superintendents of nurses in twenty-seven of the larger hospitals in New England and New York, to which they received nineteen replies. One reply stated that the physicians and interns frequently requested a high or a low enema, but that this request made no difference in the method of administration. Five taught their nurses to make no distinction between a high and a low enema. Thirteen considered a low enema to be given when the recital tube or tip was inserted less than six inches, a high one when the tube was inserted more than six inches. In general, the replies showed that nurses were taught that a high enema was expected to flush the colon, and that this could be attained by inserting the tube to a greater distance.

These replies may prove illuminating to some physicians who have not obtained the desired results from the high enemata they ordered, for many observations made with the fluoroscope have proved that attempts to insert a tube more than six inches usually result in the production of a coil of tube in the rectum, and that when the tip does enter the sigmoid a muscular contraction is induced which prevents the entrance of fluids. Therefore all enemata given in this way are low.

Still it is perfectly feasible to flush the colon, as Ellsworth and Wheatley have demonstrated, by means of opaque enemata with x ray control. The method they have found most satisfactory is to have the patient lie face down, insert the tube just beyond the internal sphincter, usually about three inches, and inject the solution, heated to body temperature, slowly with a pressure produced by not more than eighteen inches elevation of the reservoir. When the patient feels any discomfort the flow should be stopped until the sensation has passed. In this way most patients can receive nearly two quarts of fluid by rectum with little or no discomfort, or even sensation, while sometimes the lower part of the ileum becomes filled. This is a high enema.

MEDICAL EDUCATION

Education is an experiment and medical education is as experimental as any other form. The experimenters, the teachers of a subject, get notions in their heads from time to time and change their methods accordingly, lest one good custom corrupt the educational world. One generation of medical pedagogues starts its students of anatomy with the skin and works them down to bone; another starts with bone and works outward to integument. One generation teaches by lecture, the next by text; full time professors are in vogue one year and looked upon with suspicion the next. One generation thinks the course of study too brief and the next considers it too long. Hitherto the student has been driven to absorb as much as possible throughout his course; recently we hear of letting him "work out his own ideas for himself." Verily, unless human nature has mightly changed, these students, even at the baldheaded age to which medical students have now attained, are not in the least prepared for working out their own medical salvation. The teacher has failed to place himself in the student's place, but is thinking in habits of his own age, experience and enthusiasms.

After all, it is neither the medical curriculum nor the medical student that make the good doctor. It is the man himself. The man behind the book or instrument and the man beside the sick bed. When it comes to the research worker perhaps it does not make so much difference, but even these scientists are born rather than made. The addition of a few years of attendance at college to his educational career does not in the least make the student more suitable timber, either for research or practice.

More than anything else in medical training, selection, natural or artificial, would be of the greatest advantage, both to the student and to society. As it is, a considerable percentage of medical students are dropped, because the examinations show them unfitted for medical work, while others, who, from general intellectual ability, pass with credit, find the work on which they enter uncongenial and not at all what their imagination pictured it. In the words of —was it Councilman? "the study of medicine is heaven but the practice is hell."

In the "good old days" an early selection did take place. The prospective medical student had his first lessons with the physician who served as his tutor. He not only read in his office but visited the sick with him, and assisted in emergencies. He knew what the business was like, and whether he liked to be a doctor, before he went to a medical school. If he did not like the work or did not get on well with it he went into other business.

This natural means of selection is gone forever or at least for the time being; in its place some psychological test may possibly be invented to serve the purpose. Still, there is nothing like the reality, and the prospective student may well be urged by his physician friend, or educational adviser (if there be such in this day of educational mills) to do service for a season as assistant to a physician, in a dispensary, or in some other capacity where he may come into first hand contact with sickness and with the sick, and learn what it is like before spending much time and money in studying for the profession.

PNEUMONIC PLAGUE

Pneumonic plague is raging in India where thousands are dying weekly from the disease. Perhaps this epidemic is only of academic interest in this country from the medical viewpoint, although there is the chance that it may be introduced into California, unless the most stringent care is taken to exclude it. From the humanitarian aspect the prevalence of plague in Asia is of worldwide concern and it is to the interest of the race that means should be found to control the disease and if possible extirpate it. The control or extirpation of the plague is mainly a medical problem and on account of the conditions prevailing in Eastern Europe, and in Turkey and Greece in particular, the prevalence of the disease is a menace to Western Europe and possibly to this country.

In the *China Medical Journal*, January, 1923, a journal published monthly by the Medical Missionary Association of China, is an account by J. W. H. Chun, M.B., B.C. (Cantab), M.R.C.S., L.R.C.P., of the epidemic of some of the salient points of the pneumonic plague in Harbin, Manchuria, in 1921. The first epidemic in Harbin occurred in 1910-11 when the death rate was much higher than that in 1921. In fact the plague mortality in the whole of Manchuria in 1910-11 was six times greater than in the latter year. Dr. Chun assigns this remarkable change to three causes: 1. The existence of a permanent antiplague service; 2, the willing and enthusiastic report of the Chinese authorities; 3, the active cooperation of the officials of the Chinese Eastern Railways and of the Russian doctors with the Chinese staff.

Some research work was done among the contacts, and it was found that two men were plague carriers. Experiments on the action of different antiseptics on plague sputum showed some instructive facts. It was found that methylated spirit or absolute alcohol killed Bacillus pestis in three minutes. When the sputum was mixed with lime and left for thirty minutes, no growth could be obtained, while perchloride of mercury one to five hundred did not kill Bacillus pestis in sputum under ten minutes.

With regard to treatment, nothing was of avail. Two early cases were treated with antiplague serum in large doses both intravenously and hypodermically. Four early cases were injected with novarsenobillon in 0.9 doses. Intravenous injections of ensol, electrargol, formalin, sodium gynocardate and carbolic acid per os, were all tried and failed.

It would seem that preventive measures must be relied on for the abolition of plague and on account of the opposition of the people it is, at present, impossible to put these into force. The only measures which can be used are to control the epidemic as effectively as can be done with the means at hand to restrict the range of the epidemic by all available methods and especially to prevent any infective cases from leaving the country. Of course, ruthless war should be waged upon rats, which are the chief conveyers of plague.

A NEW EPOCH IN THE CARE OF THE INSANE

At last it seems as if mental disorders are to be treated with that amount of intelligence which their importance demands. That is to say, that all forms of mania are not to be classed as incurable but efforts are to be made to treat the early stages of certain mental disorders in such a manner that they may be prevented from developing into a serious condition. In this country beginnings in this direction have been made already, as most of the large American hospitals have a ward in which those who are suffering from mental derangement are kept under close observation by skilled medical men so that their affection may be classified and treated accordingly. The old conception of mental malady is dying out and with it the old not infrequently inhuman mode of treating these unfortunate mentally sick persons. It is now recognized that some forms of mania arise from a physical cause, if not wholly so at least in part, while in some cases the sick mind proceeds directly from a sick body.

With regard to dementia precox, Dr. White Robertson, a well known Scotch alienist, states that it is brought about by intestinal stasis, which causes a toxemia of the spleen in which the mental faculties are often involved. These views are supported by many distinguished British physicians and surgeons and is in strict keeping with the new trend of medical treatment initiated and developed by Sir James Mackenzie, who teaches in and out of season that in order to treat disease with any hope of success, symptoms must be to some extent overlooked and the primary cause must be diagnosed and treated conscientiously. Correct diagnosis of the originating cause of a disease is the most essential point and he who is a good diagnostician is best equipped for the work of a physician, although it must be said that the quick and reliable diagnostician is a good deal akin to the poet, "born, not made." However, if it is granted that the diagnosis and treatment of the primary cause is the most important factor for success in medical practice, and who will deny this, and if it is true that dementia precox is caused largely, if not entirely, by intestinal stasis, it naturally follows that the rational treatment of the mental disorder is to sap its progress by efficiently treating intestinal stasis. It may be mentioned that perhaps the majority of those affected mentally suffer also from disorders of the gastrointestinal tract. May it not then be well within the realms of reason to suppose that other forms of mental aberration or even disease may have their origin in a physical cause, more often than not engendered and in all cases aggravated by gastrointestinal disturbances. In any event, the recent methods of dealing with the insane, of carefully observing them in order to discover if possible the origin, physical or otherwise, of the condition and of treating this originating cause by the best known means at hand, is an epoch making new departure.

The history of the insane and their treatment make at one and the same time a fascinating and grewsome study. Up to the closing years of the eighteenth century the treatment of those disordered in mind in civilized countries was barbarous in the extreme. At the time when Jenner was conquering smallpox, the humane treatment of the insane was begun. Independently and simultaneously, the French physician Pinel and the British Quaker philanthropist Tuke instituted much needed reforms into the management of asylums. Until these men by their energy and enthusiasm were the means of the prison systems of France and Great Britain being altered for the better, nowhere in the world had the victims of mental disease been treated with kindness and a certain amount of intelligence. The examples of France and Great Britain in this direction have been followed in civilized countries and at the present time, it may be said without boasting that this country is easily in the van, so far as the treatment of the mentally afflicted is concerned and that the pioneers have been left far behind in the race to improve mankind.

Another step forward has been made recently in Great Britain. Dr. Henry Maudsley, whose specialty was the treatment of the insane, died some years ago, leaving a large sum of money made over to the London County Council for the foundation and endowment of a hospital for the insane conceived on original lines. Dr. Maudsley, somewhat before his time, was one of those who realized that those termed insane were really sick and required special treatment and special solicitude and he founded and endowed this hospital so as to carry into effect this particular object. The hospital, situated in a healthy suburb of London, consists of an outpatient department and 157 beds for inpatients, in addition to a considerable number of private rooms. The hospital is associated with the pathological department of the London County Mental Hospitals under the direction of Sir Frederick Mott and is adequately equipped for up to date treatment and for carrying on research.

It appears that we are well on the way towards understanding that mental disorder or, at least certain forms of it, proceed from natural causes and we also seem to be on the road towards discovering what these causes are. If diagnosed in time and the causes efficiently treated these forms may be arrested just as other diseases may be arrested if the primary cause is discovered and properly treated in a sufficiently early stage. As said before, a new epoch in the treatment and care of the insane has arisen and is developing. The treatment and care is based on common sense and it may not be too much to predict that mental hygiene will soon be as far ahead of existing methods of treatment as is the treatment nowadays in advance of that practised in the time of Pinel and Tuke.

OLD CURES FOR NEW

So many means have been tried for the cure of consumption that it is little to be wondered at if one of them which is put forward for a second time should seem to be new. We refer to the recommendation of inhalations of coal dust or of carbon in other form for the cure of this disease.

This sort of treatment was tried in Europe a half century since but the results do not seem to have been at all startling. In 1885 Professor Pepper, of the University of Pennsylvania, made a questionnaire study of the relation of climate in Pennsylvania to tuberculosis and malaria. In a letter on the subject received from Dr. Matins, of Luzerne County, we read: "I have known many persons apparently in decline entirely cured by inhaling the dust of the coal mines and the smoke from lard oil lamps." It is unfortunate that the correspondent did not give more accurate figures as to just how many were cured, but evidently the numbers were not sufficient to attract large interest in the socalled cure.

It was noted in England long ago that the death rate or percentage of deaths from tuberculosis among coal miners was only about half what it was among workers in other occupations. In this country the same holds true, especially among anthracite miners. The Metropolitan Life Insurance Company's experience with miners (1911-1913) gave a percentage mortality of 5.8, while for all occupied males the percentage was 20.5. These latter figures must be modified on account of the high percentage of violent deaths, but even so the percentage of deaths from tuberculosis remains very low.

While from these figures there might seem to be some ground for faith in carbon dust as a cure for consumption the proportion of disease of the respiratory organs is relatively high, so that while the coal inhaler may escape consumption (or consumption in its ordinary form) he is prone to miner's asthma, chronic bronchitis, or other disease due to anthracosis. In escaping Scylla he encounters Charybdis.

It is certain that the effects of breathing coal dust upon the tuberculous process is radically different from the effects of silica dust. Coal miners are protected against tuberculosis to a certain degree. Stone workers are very subject to it and die early. The difference in effect has been attributed of late to difference in chemical reaction of the two substances upon the lung tissues rather than to any difference in mechanical action. The lime in the coal has been given the credit for the inhibition of tuberculous activity, but the amount of lime is very small indeed. Whether the sulphur is of service in this connection has not been determined, but it is present in large amount compared with lime and certainly deserves to be taken note of.

As a cure for tuberculosis the inhalation of coal dust certainly is not to be recommended, but from its evident effect upon the lung in those who must breathe it, it deserves study in the hope that, in some other way, the introduction of carbon, sulphur, lime, or whatever, in coal reduces the mortality from the disease, may be of use in its treatment.

MALE AND FEMALE MORTALITY RATES

A condition prevailing quite generally throughout the civilized world has always been that the death rate of males has been found to be higher than that of females at every age period from birth until death. In one of its studies, the Metropolitan Life Insurance Company has found that this supposedly fixed relationship may be changing. In 1911, the mortality of the white males studied in the report was more than thirteen per cent. higher than that of the females. Up to and including 1918, this condition persisted with slight variations. In 1919, the excess dropped to about five per cent.; while in 1920, a reversal of the relationship occurred, with female mortality 2.6 per cent. above that of males. In 1921, it was still 1.2 per cent. above. In 1922, however, the condition was changed to an excess of 1.2 per cent. in male mortality over that of female. Similar relationships, it is stated, are indicated in the figures of the registration area during the corresponding years.

What these changes may mean, the report goes on to say, it is still difficult to say. Three items are mentioned as having a possible bearing on the situation—the reluctance toward improvement of the maternal death rate, the increased maternal mortality during the influenza outbreak, and the fact that there has occurred a much greater decline from pulmonary tuberculosis among males than among females. This last point is probably the only one that may be taken as being at all decisive, for it is too early to draw any general conclusions as to the other conditions, and new factors may suggest themselves as future changes occur.

The report suggests that students of public health observe the phenomenon in their respective areas and note whether or not the conditions described have been general or localized. It is possible that the condition is temporary only and may not occur again.

◆

News Items.

Birth Rate Drops, Death Rate Rises.—A decline in the birth rate and a slight increase in the death rate in 1922 was shown in provisional census bureau figures for the year announced today by the Department of Commerce. For the twenty-four states reporting birth figures, the rate for 1922 was 22.7 for each 1,000 of population, against a rate of 24.4 for 1921. For thirty-three states the death rate last year was 11.9 against 11.6 for 1921. North Carolina reported the highest birth rate, 30.2, while a rate of 18 for the State of Washington was the lowest. Death rates in the thirty-three states ranged from 14.7 for Maine to 8.1 for Idaho.

Heads McGill Medical School.—Dr. C. F. Martin was appointed Dean of the Faculty of Medicine of McGill University. He succeeds Dr. George Armstrong, resigned. Dr. E. W. Archibald was named professor of surgery and director of the surgical department of the university.

Aid Insulin Committee.—The Insulin Committee formed recently to provide free treatment with insulin in emergency cases to patients suffering from diabetes, reports hearty response to the few appeals it has sent out. A number of hospitals have already made applications for sums to be used for special cases.

Dr. Pedersen Robbed.—Sneak thieves are again visiting physicians. Dr. V. C. Pedersen, 45 West Ninth Street, has in this way been deprived of a nickel plated case marked "Special" on the cover outside, and again on the bottom inside, containing about $150 worth of urethral catheters and accessories. If this box is presented at any physician's office, aid in the arrest of the culprit will be appreciated.

Dr. Goldthwait Called.—Dr. Joel E. Goldthwait, professor of orthopedics at Harvard and one of the foremost surgeons in America, was called to active service from the organized reserves with his rank of Brigadier General in the Medical Corps for duty at the citizens' military training camps, in orders issued byMajor General Robert L. Bullard, commanding the Second Corps Area, at Governors Island.

An Appeal for Information on Maternal Welfare.—The Committee on Maternal Welfare of the American Association of Obstetricians, Gynecologists and Abdominal Surgeons is anxious to procure accurate information as to the progress each State is making in the matter of Maternal Welfare in order to formulate a report for their annual meeting in Philadelphia, in September. Dr. George Clark Mosher, chairman, Bryant Building, Kansas City, Mo., has the matter in charge.

Cancer Cases Tripled in French District.—Almost a tripling of the number of persons suffering from cancer has been reported in the District of Toulouse during the last four years, according to a communication read in the Academy of Science by Professor Romond, of the Toulouse Faculty of Medicine. The statistics cover 694 localities in eight departments. They show that the number of sufferers from the disease in 1919 was 300, and that the number increased to 362 in 1920, 585 in 1921, and 846 in 1922. For the city of Toulouse the increase in the four years was from 22 to 126 cases.

Medical Society of New Jersey.—At the one hundred and fifty-seventh annual meeting of this society, held in Atlantic City, June 21st to 23d, the following officers were elected: Dr. Willis P. Eagleton, Newark, president; Dr. Alexander MacAlister, Camden, first vice-president; Dr. Archibald Mercer, Newark, second vice-president, and Dr. Lucius F. Donahue, Bayonne, third vice-president; recording secretary, Dr. John Bennett Morrison, Newark; corresponding secretary, Dr. William J. Carrington, Atlantic City, and treasurer, Dr. Elias J. Marsh, Paterson. Next year's meeting will also be held in Atlantic City.

Dental Clinics Aid Million in Schools.—Continuance of dental clinics in school buildings, rather than in centres where a number of schools could be served, has tended notably to increase success of school dental work, the Department of Health reports in its monthly bulletin. The number of dental clinics established by the Department of Health has steadily increased and at present there are twenty scattered throughout the five boroughs as follows: Five in Manhattan, four in the Bronx, six in Brooklyn, three in Queens, and two in Richmond.

Maternity Hospital to Build on Fifth Avenue.—The Jewish Maternity Hospital has purchased four lots at the northeast corner of Fifth Avenue and 108th Street, on which it will erect a twelve story hospital building to cost about $750,000. The site has a frontage of 75 feet on the avenue and 125 feet on 108th Street. The new hospital as planned will include 150 beds, almost three times the capacity of the present building at 270 East Broadway, and will include laboratories for research. More than $1,000,000, most of which has been raised by subscriptions, will be involved in the transaction.

Foreign Medical Congresses.—The program for the next congress in Brussels of the French Association of Pediatrics has already been announced. The congress takes place in September. The congress of the Association for French Gynecologists and Obstetricians will be held on August 9th to 11th in Geneva; The National Association for the Prevention of Tuberculosis will hold its ninth annual meeting in July in Birmingham, England; The National Association for the Prevention of Infant Mortality and the National Baby Week Council will hold a joint conference on infant welfare in London on July 2nd to 4th.

Rockefeller Institute Appointments.—The board of scientific directors of the Rockefeller Institute for Medical Research has announced the following promotions and appointments for the coming year: Dr. Oswald T. Avery and Dr. Walter A. Jacobs, associate members, have been made members; Dr. Michael Heidelberger, Dr. Christen Lundsgaard, Dr. Peter K. Olitsky, and Dr. Louise Pearce, associates, have been made associate members; Dr. David I. Hitchcock, Dr. Frederic M. Nicholson, Dr. Henry S. Simms, and Dr. Leslie T. Webster, assistants, have been made associates, and Dr. Mimosa H. Pfaltz, a fellow, has been made an assistant.

The following new appointments are announced: Associate members, Dr. Jacob J. Bronfenbrenner and Dr. Paul A. Lewis; associates, Dr. Oskar Baudisch, Dr. Stuart Mudd, and Mr. Herbert L. J. Haller; assistants, Mr. Arnold M. Collins, Dr. John H. Crawford, Dr. Robert Elman, Dr. Joseph H. B. Grant, Mr. Moses Kunitz, Dr. Cecil D. Murray, Dr. Everett S. Sanderson, Dr. David T. Smith, Mr. James Vander Scheer, and Dr. Lars A. Welo; fellows, Miss Gladys Bryant, Dr. Charles Korb, Miss Dorothy Loomis and Dr. Elmer L. Straub. Dr. J. Howard Brown, an associate in the department of animal pathology, has accepted a position as associate professor of bacteriology at Johns Hopkins Medical School, Baltimore, Md. Dr. Fred A. Taylor, an associate in chemistry, has been made head of the department of biochemistry at the William H. Singer Memorial Research Laboratory, Pittsburgh, Pa.

LONDON LETTER

(*From our own correspondent.*)

London, *July 5, 1923*

THE CANCER CAMPAIGN IN GREAT BRITAIN.

A campaign against cancer has been inaugurated and is in progress in this country, and although belated, it appears that the fight against the disease will be waged with persistency and vigor. It is recognized that cancer is increasing, that it is a public menace, that money spent in research is money well spent, and that money expended in an educative propaganda is well worth while. A call to arms has been issued in the shape of a letter to the lay press signed by leaders of the medical profession and other well known men, among them being Sir Napier Barnett, head of the Hospital Service of the British Red Cross. Lord Dawson of Penn, physician in ordinary to the King; Sir Thomas Horder, physician at the Cancer Hospital, Fulham; Mr. J. P. Lockhart Mummery, F. R. C. S., senior surgeon at St. Mark's Hospital for Cancer, and the Hon. Sir Arthur Stanley, chairman of the Joint Council for the British Red Cross Society and the Order of St. John of Jerusalem.

In the letter referred to, it is stated that cancer, in spite of the advances which have been made both in diagnosis and treatment, is still the most common single cause of death in persons over thirty years of age, and is becoming so in an increasing degree. During 1920, in England and Wales, nearly forty-three thousand persons of thirty years and upwards died from cancer. In 1921, the last year for which the Registrar General's figures are available, the corresponding number was 45,328. During that year one in every seven deaths from the age of thirty onwards was caused by cancer. We are still ignorant both of the causation and cure of cancer. Many other diseases have yielded their secrets to patient investigation, and there is no reason to suppose that the problem of cancer will not eventually be solved. Yet thousands of suffering men and women, and those who suffer with them, are asking how long they must wait, and if there is nothing that can be done to hasten a discovery which will bring relief to those whose outlook is today so hopeless. The tenor of the letter of appeal is for funds to be spent chiefly in research work, laboratory and clinical, to found a movement which will coordinate and support research in cancer throughout the British Empire.

As Sir Thomas Horder has pointed out, it is intended that the money subscribed to the fund for the prosecution of the campaign against cancer shall be received through the Red Cross Society, which has placed its organization and machinery at the disposal of the council of the campaign. It is not only a question of laboratory research, there are also the large questions of accurate statistics of clinical bedside observations, of the collection and classification of literature for reference, and of the critical examination of methods of treatment advanced by members of the profession and laymen.

Sir Thomas Horder characterized the province of the executive committee as that of a clearing house of information regarding all aspects of cancer and he laid stress on the value of team work in solving a problem of this nature. It should be said that the council disclaims any intention to interfere with the work already being carried out. Individuals and institutions now working on the cancer problem will be helped and encouraged, and where practicable financially assisted. In this way investigation can be carried out simultaneously along many lines, and the results of these inquiries will be brought into the common stock of knowledge. A discovery in any one branch will be made known to all, and may lead to discoveries in other branches. It is from this coordination of effort that the best results are hoped for.

One of the individual workers in cancer research is Dr. J. Shaw Mackenzie, who for several years in the laboratories of King's College, London, has been carefully and patiently working on his theory that in cancer there is defective lipolysis and utilization of fats, with excess of blood fats and lipoids, and that the treatment indicated is to stimulate lipolysis in the tissues.

The Federation of Medical and Allied Services has had much to do with inducing the public to interest themselves in health matters and, as its president, Sir Berkeley Moynihan said at the annual dinner held in London on May 29th last, that if cancer was only to be cured by early diagnosis it was essential that the public shall be educated to recognize the early signs of cancer. The public in this country are ignorant of the benefits to health to be derived from the carrying out of medical research. Not understanding its value they are inclined to believe that money expended in this direction is money more or less wasted. The community must be educated to appreciate the gain to the general health brought about by medical research and it is fitting that such education should begin with cancer, the most deadly and increasing disease of civilized people.

THE ROCKEFELLER GIFT TO UNIVERSITY COLLEGE.

On May 31st last the King and Queen visited University College and University College Hospital, London, for the double purpose of laying the foundation stone of the new obstetrical hospital and of opening the new anatomy building of University College. The Rockefeller Foundation gave £1,205,000 to University College and University College Hospital to enable a scheme for the advancement of medical teaching and research in this country to be carried out, of which the new building for anatomy, and the new obstetrical hospital and nurses' home are part. The King in his speech pointed out that there can be but few instances on record in which any institution like University College and Medical School has received such a sum from a single benefactor in a single gift. And the magnificent generosity of the Rockefeller trustees is the more impressive since it is bestowed by a citizen of the United States upon a college and hospital in London, and thus upon the people of Great Britain and the Empire. We understood that this college and medical school were selected by the Rockefeller trustees for their benefaction from among many equally distinguished institutions, partly because the situation was factor in a single gift. And the magnificent gener- partly because the close connection of the hospital and medical school with the college provided favorable opportunities for that intercourse between medicine and other branches of learning which was the surest defense against the evils of a narrow specialism. But he also understood that the trustees were chiefly influenced by the establishment at this college of what had come to be known as the unit system of medical teaching, and that being convinced of the value of this reform, they desired to supply the resources for carrying it out in an English university on a scale worthy of its importance both to education and research. The King then gave a description of the unit system.

The Queen expressed her great satisfaction at the establishment of the obstetrical unit and of the maternity hospital of which it formed a part. The present position of the care of maternity and infant life in this country was not wholly satisfactory, and there was no doubt that every year many lives were lost in childbirth and many women suffered injuries to health which might be prevented if better facilities for treatment were available. Two of the main requisites for bringing about a better state of affairs were to ensure that medical men were well and efficiently trained for their work and to provide maternity hospitals in which patients might be received. The Queen expressed her gratification that the claims of the nursing service had not been overlooked, provision having been made for the establishment of a new nurses' home.

No representative of the Rockefeller trustees was able to attend, but Mr. Post Wheeler, councillor of the American Embassy, came with his wife, and Dr. G. G. MacLean, director of the American University Union in Europe, was also present.

BIRTH RATE AND DEATH RATE IN GREAT BRITAIN.

In the three months, January, February, and March of this year, the birth rate in England and Wales was the lowest for any first quarter since the war. According to the Registrar General's returns the births registered numbered 192,970 or 14,603 fewer than in the corresponding period of 1922. This figure represents a rate of 20.5 per 1,000 of the population and shows a heavy decline from the record of 29 in 1,000 attained in the first quarter of 1920. The death rate for the quarter, at 13.3 in 1,000, also established a new record.

LATIN AMERICA LETTER.

(From our own correspondent.)

BALBOA HEIGHTS, *June 20, 1923.*

BUBONIC PLAGUE.

So far as the Panama Canal is concerned, bubonic plague is an ever present sanitary menace. Yellow fever has been relegated to hygienic oblivion; typhus has never gained a foothold in a moist sea level climate; smallpox can not spread where vaccination is enforced; cholera can not become epidemic in an environment with a good water supply and adequate sewerage, but there is always the danger that if plague should penetrate the line of sanitary defence maintained by the Health Department of the Panama Canal that it might extend to the jungle rats and create an ineradicable pest focus which would permanently injure an international industrial plant in which the American people have invested over half a billion dollars. Plague is essentially a seaborne disease, hence seaports are ever exposed to it and the Panama Canal, as the focus to which converge the lines of maritime commerce, if without adequate sanitary protection would therefore be exposed to infection from almost every quarter of the globe.

At the present time bubonic plague is a major pestilence of worldwide distribution. During the calendar year 1922 either human or rodent cases have been reported in California, Mexico, Ecuador, Peru, Chile and Brazil, in the Western Hemisphere; in Europe, in Great Britain, France, Portugal, Spain, Greece, Turkey and on the Island of Rhodes; in Africa, in Egypt, Algeria, Tunis, the Azores and Cape de Verde Islands, Senegal, Portuguese West Africa, the Union of South Africa, Madagascar, British East Africa and Mauritius; in Asia Minor, in Smyrna, Mesopotamia, Palestine and Syria; in Asia, in India, Indo-China, Siam, Ceylon, Java, the Philippines, China and Japan; Australia and Hawaii are also infected.

How very real this danger is may be shown by the fact that from January 1 to 31, 1923, there occurred in Peru alone 151 cases of bubonic plague with fifty-nine deaths. The cases were distributed through twenty localities many of which were far apart. The Panama Canal is taking every precaution for the exclusion of the disease from its territory. All wharves and docks are of rat proof construction and by constant use of traps and poison the rodent population is kept in check. Ships are required to breast off from wharves and to apply satisfactory rat guards to all mooring lines. Unprotected hose lines, savealls and the like must be raised at night and gangways either raised or guarded by a watchman. All ships docking at Panama Canal ports must be fumigated at stated intervals for the destruction of rodents. Vessels destined for Panamanian ports are required to enter through Canal ports thus ensuring for the republic the same protection as the Canal Zone itself receives. There has been a consistent policy on the part of the Health Department to assist and stimulate other countries to attack their plague eradication or prevention problems and a fine spirit of cooperation has been thus secured between the health authorities of the Canal and those of nearby countries. In this mutual notification and uniformity of quarantine procedure has been secured.

LAYING THE CORNERSTONE OF THE GORGAS MEMORIAL INSTITUTE.

To those who live out on the fringe of things it is a great deprivation to lose contact with fellow workers in the profession at home. It was therefore with great joy that a committee of local Fellows of the American College of Surgeons, comprised of Dr. Augusto S. Boyd, Dr. A. B. Herrick, Dr. R. W. Runyan, Dr. T. W. Reeder, Dr. E. A. Bocock, Dr. H. C. Fisher, Dr. W. C. Rucker, Dr. H. A. Webber, Dr. D. S. Fairchild, and Dr. T. J. Leary, on the morning of February 18th met the *S. S. Vandyck* with a party of 115 Fellows of the American College of Surgeons and 140 friends and wives aboard. The party was taken to Gatun Locks by special train and after inspecting the locks and spillway, again boarded the train and proceeded to Gamboa, where the tug *Favorite* was taken through the cut to Pedro Miguel. Thence the party went to Panama by train. In the afternoon they took part in the laying of the cornerstone of the Gorgas Memorial Institute of Tropical Medicine in the City of Panama, the exercises being conducted under the direction of the chairman of the local committee, Dr. Augusto S. Boyd.

The institute is to occupy a point of land jutting out into beautiful Panama Bay and will adjoin the grounds of the new Santo Tomas Hospital, which is being erected by the Republic of Panama. The exercises took place in a flag covered stand, in the centre of which stood a bronze bust of the late Major General William Crawford Gorgas, M.C., U. S. A., to whom the institute is to be a memorial.

His Excellency, Dr. Belisario Porras, President of the Republic of Panama, made the dedicatory address, in the course of which he said: "Gorgas destroyed the morasses of death and redeemed the tropics. I can still remember, and it seems to me a horrible nightmare, the time fifty years ago when on my way to Bogota to finish my studies I found it indispensable to spend the night in Colon. Sleep during that night was impossible for me because of the constant and tormenting bites of the mosquitoes whose incessant buzzing smote on my ears as though they were the discordant notes of an infernal serenade. Those minute tormentors were so numerous that by clutching at the apparently empty air I caught handful after handful of them. Neither can I forget conditions as they prevailed when I returned from college ten years later and entered the employ of the French Canal Company. From that time I was able to realize, or at least suspect, the underlying cause of the Frenchmen's failure in their attempt to construct the trans-Isthmian waterway. They constructed beautiful residences and tree lined avenues and admirably organized their offices; but they did nothing, in fact they knew nothing, about tropical sanitation and apparently never suspected its worth. Thanks to Gorgas, those days have passed never to return, and our tropical home has become one of the world's health resorts. The monument which we shall erect here will be an expression of Panama's gratitude to the man who proved beyond peradventure of a doubt that the tropics could be made habitable for all races."

Dr. Boyd spoke on behalf of the local profession and Dr. Franklin H. Martin for the American College of Surgeons and at the close of the ceremonies bronze commemorative medals and pamphlets, containing President Porras's address in Spanish and English, were distributed. In the evening President and Mrs. Porras held a reception for the visitors at the Palace, at which time Dr. John G. McDougall, of Halifax, the second vice-president of the college, conferred the Honorary Fellowship on Dr. Augusto Samuel Boyd. The visiting surgeons and their party sailed for Cartagena, Colombia, *en voyage* to Buenos Aires, the following day.

Although the Panaman Republic has not yet constructed the buildings which the institute is to occupy, and the endowment fund which the citizens of the United States are to raise is believed to be still incomplete, the scientific director of the institute, Dr. Richard P. Strong, is on the ground and it is reported that he will begin actual research work very shortly in the new laboratory building of Santo Tomas Hospital. The laboratory, which is one of the five completed buildings of the twelve which will comprise the new Santo Tomas Hospital, is a two story concrete structure adequate in size for all the work of the hospital and at the same time to perform the functions of a board of health laboratory for the republic. It contains a morgue, autopsy room and crematory in addition to the usual work rooms of a laboratory. The venereal, isolation, tuberculosis and maternity wards are of the best modern construction and equipment, and are completed. The completed hospital will cost $3,000,000 and will have 900 beds. It will replace the original Santo Tomas Hospital, which was begun in 1696.

RECENT CANAL ZONE VISITORS.

Among the distinguished medical men recently visitors on the Canal Zone were Dr. Lewis Stephen Pilcher, editor of the *Annals of Surgery;* Dr. Victor Heiser, of the International Health Board; Dr. Oscar Dowling, State Health Commissioner of Louisiana; Dr. Truman W. Brophy, of Chicago, and Dr. Samuel J. Mixter, of Boston. The maneuvres of the United States Fleet also brought Captain James C. Pryor, M.C., U.S.N., Fleet Surgeon of the United States Fleet, and Captain William H. Bell, M.C., U.S.N., Fleet Surgeon of the Battle Fleet.

LETTER FROM GENEVA

(*From our own Correspondent*)

Geneva, *March 20, 1923.*

POSTTRAUMATIC PULMONARY TUBERCULOSIS.

More work on posttraumatic pulmonary tuberculosis has been lately accomplished at Lyons, a good deal of it having been carried out by Dr. C. Euthymion, who finds, as others have, that this condition is uncommon following penetrating wounds or severe contusions of the thorax. These lesions may play an important part in revealing or aggravating a preexisting tuberculosis, although latent. It is, however, maintained that thoracic contusions and the inhalation of asphyxiating gases have a more marked phthisiogenic action than bullet wounds, a conclusion reached after a study of 737 cases.

It may be recalled that Sergent, of Paris, whose experience during the war was vast, has also pointed out the infrequence of pulmonary tuberculosis following thoracic wounds, placing it at 9.04 per cent., and he is of the opinion that it is not the trauma *per se,* but its consequences that open the door to tuberculosis. The delicate question to decide is clearly the right interpretation of a real causality between the trauma and the signs of tuberculosis observed, after a careful examination, which should eliminate all cause of error. The first symptoms must develop rather soon after the receipt of the injury, while the lesions discovered must not be those of a somewhat advanced tuberculosis, if any relation exists between the trauma and the tuberculous process.

Euthymion was able to follow his cases systematically immediately after the injury, so he admits that the date of the onset of the pulmonary process must be the time when bacilli are first detected in the sputum or at the time of military revision. Thus understood, the lapse of time between the receipt of the trauma and the detection of the tuberculosis is variable, extending from one to twenty-three months, which is evidently the maximum. The duration of the real period should be below this maximum.

As to the seat of the tuberculous localization, in direct traumata—wounds or contusions—it in most instances corresponds with the area of the injury or its neighborhood, but it may arise at a somewhat distant point from this. Following the inhalation of asphyxiating or irritant gases the lesions are usually to be found at the apex following upon a phase of acute bronchitis. Other than for its etiology, there is nothing which distinguishes posttraumatic tuberculosis, from the clinical or pathological viewpoint, from the various forms of the affection due to other usual etiological or pathogenic factors of this malady. As to the evolution of these traumatic pulmonary cases, it would appear that they offer three rather distinct forms: 1, an evolutive form, the most frequent, similar to the classical fibrocaseous type; 2, an acute or subacute form progressing rapidly to death, and, 3, an abortive form ending in an apparently complete recovery in a few months with disappearance of the local signs. The postgaseous cases present a congestive onset with hemoptysis; the lesions either extend rapidly or the process may become abortive in a very short time and recovery take place. To differentiate it from a nontuberculous bronchitis animal inoculation must be resorted to.

ARSENICAL PREPARATIONS IN SYPHILIS.

Too much consideration cannot be given to the arsenical products at present so extensively used in the treatment of syphilis, and for this reason attention should be given to some recent utterances of Milian, of Paris, who has done so much to advance this treatment. The first precaution, when giving an intravenous injection, is to give it slowly, and Roger's experiments in this direction are conclusive. This rule is imperative in the administration of the arsenobenzole because, when they give rise to accidents, these occur quickly.

Let us suppose that a nitritoid paroxysm arises one or two minutes after the beginning of the injection. If the latter has been given slowly—and the solution well diluted as it should be—since it requires about ten minutes to complete the injection, this can be stopped the minute the first symptoms appear, thus controlling the intensity of the paroxysm. On the other hand, if a concentrated solution is used, the probability will be that most of the drug will have entered the circulation when the attack begins, so that all control over it is lost, and Milian very correctly says that injections made by Ravant's technic cannot be given with the necessary slowness.

Dilute solutions only should be given and precautions similar to those employed against anaphylaxis should be taken, by first injecting one cubic centimetre of the solution, and then waiting about fifteen seconds and injecting another cubic centimetre. Do this a third time and then slowly inject the rest of the solution. This technic should be adopted in every case when the treatment is begun and from what has been observed in the Geneva clinics, I would add that it should be the routine practice if accidents are to be avoided.

As you know, Milian introduced the use of adrenalin as a treatment of nitritoid crises and he very rightly objects to its indiscriminate use as a prophylactic, because as no reaction takes place after its administration the practitioner, deceived by this fact, is apt to give a too large dose of the arsenical product so that accidents occur later and then the adrenalin administered may not be effective in counteracting them.

TREATMENT OF LOCOMOTOR ATAXIA.

And now that we have been discussing the question of injection of arsenical preparations, allow me to refer to the treatment of locomotor ataxia at its onset and also to make a few remarks on the proper manner of giving intravenous injections of the arsenical and mercurical products. When the physician detects the very early signs of a commencing tabes dorsalis, the patient presenting pain of the radicular type, ocular disturbances, such as paralysis of the external rectus, unequal and irregular pupils, and paresis of the pupil reflexes to light, vesical and genital disturbances, absence of the osteotendinous reflexes, anal pruritus and Romberg's sign, an extremely energetic antisyphilitic treatment should be begun immediately. For a long time it had been supposed that mercurial treatment was without effect on the evolution of locomotor ataxia and some observers even went so far as to pretend that the treatment might aggravate the disease, but in reality, at present, with the newer therapeutic agents at our command, these conceptions are not only erroneous but are actually dangerous. By taking locomotor ataxia in hand at its onset and attacking the process by energetic treatment, not only can the progress of the disease be controlled, but an amelioration of all the symptoms may be obtained as well, to such an extent in some cases that it is about equal to a cure.

But it must be understood that the ingestion treatment is absolutely without effect, that intramuscular injections can only be a complementary treatment destined to continue the good effects resulting from intravenous injections, and that the only treatment that gives favorable results in the process under consideration is the intravenous method. Unquestionably, this procedure offers some disadvantages, the first of which is that it requires considerable skill on the physician's part, otherwise local accidents arise that are not devoid of gravity. On the other hand, this procedure obliges the patient to make frequent visits to the physician, which is a loss of time and is expensive, since the treatment must be prolonged. It is consequently the duty of the practitioner to make this clear to the patients in the latter's interest.

As has been said, intramuscular injections are absolutely insufficient. Injections of gray oil are useless; those of calomel in oil recommended by Babinsky are very potent, but unfortunately, regardless of the various improvements made in the preparation of this oil, many patients are unable to tolerate it on account of the unbearable pain to which it gives rise, so that its use should be restricted to tabetics with muscular anesthesia. In them it works wonderfully. Finally, injections of biniodide or benzoate of mercury are useless therapeutically. Therefore, the treatment consists of injections of cyanide of mercury and novoarsenobenzol.

The injections of cyanide of mercury should be given in series of fifteen, at the rate of one every second day.

(*To be concluded.*)

Book Reviews

DIET

Right Food the Right Remedy. By Charles C. Froude, B.Sc. With an introduction by Royal S. Copeland, A. M., M.D. New York: Brentano's, 1923.

The subject matter of this book consists of a discussion at length of the subject of diet, principally for the adult, although a small amount of attention is given to the diet during infancy and childhood. It is treated from the viewpoint of a follower of J. H. Tilden, who runs a sanitarium in Denver, Colo., and publishes a magazine called *The Philosophy of Health.* Tilden has built up a large following all over the United States, so that a physician who is practising dietetics can see from the questions of many of his patients that they have been influenced by the Tilden method.

The following points are brought out in this book: 1. The harmful effects of refined sugar and refined cereals. 2. The separation of the concentrated starches from the heavy proteins, not permitting them at the same meal. 3. The separation of the acid fruits from the concentrated starches. 4. The importance of raw foods, such as fruit and green vegetables, eaten as salads. 5. The emphasis upon the alkalinity of these foods and the prevention thereby of acidosis. 6. The prevention of the tendency to overeat. 7. The cure for the latter is the use of one concentrated article of food at a meal.

It would be well for the medical profession to read such a book as this in order to familiarize themselves with a method which has influenced so many people. The book is rather lengthy and too complicated in its lists of foods. The letters of the alphabet are not sufficient in number to list the various classes into which the author divides foods. However, the good points of the book are so many that it is worth reading to obtain them.

DIETETICS

Vorlesungen über Diätbehandlung innerer Krankheiten. Von Prof. Dr. H. Strauss. Berlin: Verlag von S. Karger, 1922.

In this fourth edition on his book on dietetics, Professor Strauss, the well known Berlin clinician, shows how much can be accomplished by diet in the successful treatment of disease. Strauss lays stress on the necessity of sufficient nutrition in diet used over long periods. For short periods of time a deficient diet is permissible, provided it meets the needs of the organism to combat the disease. Artificial foods are not essential under ordinary circumstances. In febrile conditions and in debilitated persons, however, they play an important part. All artificial foods should be palatable.

The book can be recommended.

GALLBLADDER

Chirurgie des Voies Biliaires. By Henri Hartman. Paris: Masson et Cie, 1923.

This volume is a collection of monographs upon the biliary passages. It is by far the most complete and satisfying work on the gallbladder the reviewer has seen. The authors take up thoroughly the gross anatomy of the gallbladder and biliary passages with a most complete bibliography. The article on pathogenesis of gallstones and cholecystitis is a most fascinating article to read told in a delightful style. Like most European articles, however, it does not give sufficient credit to some of our Amercian surgeons. No reference is made in this article to the splendid work of Peyton Rous or Evarts Graham.

The fifth chapter takes up thoroughly the etiology and biology of cholecystitis. There are a number of well reproduced photomicrographs and pictures of gross specimens of cholecystitis with and without stone. The operation is very well discussed with a thorough bibliography and satisfactory illustration. The reviewer thoroughly recommends this work as it is most painstaking and complete.

GALLBLADDER DRAINAGE

Nonsurgical Drainage of the Gall Tract. By B. B. Vincent Lyon, M.D. Philadelphia: Lea & Febiger, 1923.

This book deals with the newer methods of examining the bile directly as it flows into the duodenum. Lyon presents to the medical profession the diagnostic and therapeutic value of nonsurgical drainage of the biliary system. In treating duodenal ulcer by duodenal feeding Lyon drains the gallbladder once a week in order to prevent the bile from becoming static.

Gallbladder drainage is of practical importance in the treatment of early states of biliary stasis and simple catarrhal jaundice. It is useful, first, as a means of diagnosis of biliary diseases; second, as an alternative method of treating many types of gallbladder and duct disease, in which the question of the need of surgery is not yet definitely settled; and third, as a supplementary method of continuing, postoperatively, the surgical principles of drainage in those cases incompletely cured by surgical measures alone.

The book contains numerous valuable points of practical use to the general practitioner and is therefore recommended as a valuable addition to his medical library.

ESSAYS

Outspoken Essays. By William Ralph Inge, C.V.O., D.D., F.B.A. London: Longmans, Green & Co., 1921.

W. R. Inge is Dean of St. Paul's, London. The essays in this volume were written before and during the World War, and were first published individually in prominent British reviews, which doubtless accounts for the considerable amount of repetition in the volume. The various titles are: Our Present Discontents, Patriotism, The Birth Rate, The Future of the English Race, Bishop Gore and the Church of England, Roman Catholic Modernism, Cardinal Newman, St. Paul, Institutionalism and Mysticism, The Indictment Against Christianity, and Survival and Immortality.

The book is much too serious and full of meat for a brief review to be able to do justice to it. It will repay reading by any thinking person interested in the solution of national and world problems that led up to the war—hence, perhaps, that will lead to future wars—and caused by the war. Some of the essays treat religious and ecclesiastical subjects, and the chief impression these make on the mind of the reader is, perhaps, that here at last is a churchman not at variance with the orthodox church, yet who is able to recognize that the socalled conflict between religion and science is a most unnatural warfare, the contradictions of which are intolerable and must be resolved by earnest and openminded thinking. The essays on national and racial subjects indicate that the writer has sound sociological and psychological knowledge for a basis, and, as in the case of the religious discussions, that his attitude of mind is exceptionally liberal and broadminded. Probably the essays of greatest interest to a physician are Patriotism, a study of racial and national differences; The Birth Rate, a survey, historical and statistical of the subject; and The Future of the English Race, in which the author summarizes his conclusions in the sentence: "The nation that first finds a practical reconciliation between science and idealism is likely to take a front place among the nations of the world."

Medicoliterary Notes.

Psychology and Morals is the title of a book by J. A. Hadfield, M. B., lecturer in psychology at King's College, announced for this month by McBride. The author has developed a special psychological method and technic for treating some of the problems of human conduct, which he describes in this volume.

* * *

The Manhattan Trade School for Girls, conducted by the Department of Education of New York City, has created a special branch to be called the Trade Extension Classes, the aim of which is to give individual attention and special instruction to girls who have been unable to adjust themselves to their school work, with a view to discovering the particular line of work for which they are best fitted. The trades taught are household work, sewing, both by hand and by machine, millinery, paste and glue work, laundering and simple processes of the skilled trades.

* * *

Probably the largest mental hygiene meeting ever held was addressed recently in the amphitheatre of the Sorbonne, Paris, by Clifford W. Beers, secretary of the National Committee for Mental Hygiene. . . . Mr. Beers is now in Europe in the interests of an international congress on mental hygiene. Over 3,500 persons heard Mr. Beers's address and 2,000 more were unable to get into the building, according to word that has been received at headquarters.—*Mental Hygiene Bulletin.*

* * *

In spite of the fact that the bubonic plague is always in Java, it causes very little comment among the natives and few precautions are taken to prevent or check it, according to William Ferguson, of Melbourne, Australia, who was recently in New York on his way around the world. "Little Java has a population of 38,000,000. It would be impossible for that enormously fertile island to accommodate such a population if it increased normally. It is kept within limits only by the fact that fifty per cent. of the babies die before they are five years old."—*New York Times.*

* * *

The July *Century* contains several interesting articles on sociological subjects, among them, Four Months in a Model Factory, by Annie Marion MacLean; Southern Prisons, by Frank Tannenbaum; and Prisons and Prison Labor, by Adolph Lewisohn.

* * *

In *Harper's Magazine* for July, Katherine Fuller Gerould discusses modern publicity methods and criticizes them especially for pandering to the public's "inordinate curiosity" about private and personal matters. She blames the papers for ministering to this appetite, even though "they can have been only accessories after the fact." Another interesting article is by Henry C. Emery on the business and commercial morality of the Chinese.

* * *

"Aren't We All?" is a delightful and most refreshing comedy for a hot summer night—or for any time, for that matter. Cyril Maude as the kindly, jolly, but rather rakish Englishman, is almost perfect in his part. And even on the hottest nights, he is graciously willing to add to his labor by very charming and witty little curtain speeches.

* * *

Andrew A. Gour, a Chicago professor of medical gymnastics, has just published a book entitled the *Therapeutics of Activity,* in which he makes an urgent plea for the restoration of the socalled old time dances. He considers them to be activities developing not only the physical and mental sides of the personality, but also the moral, in that they encourage and demand discipline and restraint in contrast to the utter lack of every inhibition demonstrated by so many of the dances of the present day.

* * *

Suggestions for vacation reading among recent works of fiction by popular authors might include *The Garden Party,* by Katherine Mansfield; *Lady Into Fox,* by David Garnett; *A Lost Lady,* by Willa Cather; *The Lengthened Shadow,* by W. J. Locke; *Kai Lung's Golden Hours,* by Ernest Bramah; *The Eighth Wonder, and Other Stories,* by A. S. M. Hutchinson; *Restoration,* by Ethel Sidgwick; *The End of the House of Alard,* by Sheila Kaye-Smith; *Men Like Gods,* by H. G. Wells; *A Son at the Front,* by Edith Wharton; *Raw Material,* by Dorothy Canfield Fisher; *Young Felix,* by Frank Swinnerton; and *The Don Juanes,* by Marcel Prevost. A few of these have not as yet been published, but all are announced as summer books.

Among biographical works that should be of interest to the physician to be available this summer are *Samuel Adams,* by R. V. Harlow, which is described as a psychoanalytical study; *The Story of the Development of a Youth,* by Ernst Haeckel; *Famous Judges and Famous Trials,* by Charles Kingston; *Life of Cesare Borgia,* by Rafael Sabatini; *Life of Pierre and Marie Curie,* by Madame Curie.

The New Republic for July 25th has an article by Paul Kammerer, the Austrian scientist, now working in England, entitled Inheriting Acquired Characteristics.

Practical Therapeutics

THE TREATMENT OF SENILE PRURITUS ESPECIALLY WITH SILICIC ACID

By Friedrich Luithlen, M. D.,
Vienna, Austria.

In order to carry out a successful treatment of senile pruritus, it is necessary to determine accurately what processes in the general organism and in the skin tissue lead to the symptoms. Various anomalies of metabolism, such as gout, arthritism, diabetes, etc., as well as intoxications from the intestinal tract, may produce pruritus in aged persons. This may also be caused by a hypersensitiveness toward some substances, which are usually introduced with the food; a pruritus may, therefore, also appear as a partial phenomenon of anaphylactic processes in the skin. But if we exclude carefully all the cases in which we can demonstrate external and internal causes as exciting factors, there still remains a group of diseases, in which we attribute the pruritus only to the peculiar condition of the skin and must attribute it to the age of the individual. Only those cases in which there is no external injury, no metabolic disease and no intoxication or hypersensitiveness of the skin should be considered as senile pruritus and only such cases are discussed in this article.

How does it come about that the skin of an individual, which shows no disease, in spite of careful nursing, presents such severe symptoms, apparently without any cause, as are seen in the disease picture of senile pruritus? The etiology of this affection is still uncertain and we are even compelled to draw our conclusions regarding the nature of the processes which occur in the skin, for the most part, from the course of the disease and the results of treatment. In this disease we frequently obtain evidence that the train of thought was the correct one through the effect of our treatment.

The vital activity of the skin, especially its tendency to inflammation, may be influenced by nutrition and intoxications. I have shown previously that changes in the mineral metabolism, namely, slight deviations of the base equivalent balance of the relationship of the individual cations of calcium, magnesium, potassium and sodium to one another, change the biological processes of the tissue. Chemical investigations in connection with the experimental findings in animals presented the evidence that the reaction of the skin is influenced by its chemical structure. At the International Congress of Dermatology in Rome (1912) I lectured upon this subject and proposed to create a physiological chemistry which is to make further advances in this direction. The biological processes of the skin are, therefore, dependent upon their chemistry; this has been proved previously by myself in regard to the mineral metabolism. It is very likely that this statement also holds good for all the other metabolic processes, including also those of internal secretion.

If we wish to establish a therapy in a certain case, we must take into consideration the entire individual, the bearer of this skin; we must determine definitely his general condition and his metabolism, and we must, finally, observe the skin carefully and get an idea of the underlying anatomical conditions.

Take, for example, a case of senile pruritus. We have before us an old individual who presents senile processes in his entire organism, without being able to discover any definite disease which might explain the cause of the itching. The skin itself is flaccid, dry, exfoliating, showing a poor circulation: the anatomical picture corresponds with the clinical picture and shows retrogressive processes of the tissue. The external therapy indicated includes various salves for the dryness of the skin and an attempt should be made to soften the skin and to induce a more vigorous vascularization of the tissue with hot ablutions, sweat baths, sulphur baths and other thermotherapy. The internal therapy should include those remedies which we know lead to a vascularization of the tissue, namely, sulphur, arsenic and iodine. Internal hydrotherapy, such as the intravenous administration of isotonic and hypertonic solutions, which produce a perfusion of the skin and a change in the tissue juice, are frequently given. In a similar way, the methods of colloid therapy, venesection, serum and protein therapy and such injections as lead to disintegrating albumin (turpentine, hypertonic sodium chloride solutions, etc.) also lead to improvement under certain conditions.

We must remember, however, that arsenic and iodine and the colloidal therapeutic remedies lead not only to a change in the circulation of the skin, but also to a vast alteration of the organism and exert a powerful influence upon the relationships of internal secretion. This is very important, as in senile pruritus there is a senile condition of the skin which may be traced to retrogressive processes in the activity of the organ itself and in the function of the other endocrine glands. For this reason we frequently effect cures with organotherapy. We either administer the hormones of the generative glands, the absence of which is apparent in the particular case, or we endeavor to arouse and to regulate the activity of the glands of internal secretion by administering thyroid gland. But at the same time we must not overlook the fact that the skin, *per se*, is an independent organ, to which we must assign its own internal secretion. According to the correlation which exists among all the organs of internal secretion, we can well imagine that the administration of thyroid gland, with its powerful influence upon all endocrine glands, also acts upon the metabolism of the skin, which has also been proved to me by experimental investigations. Therefore, in some cases we are enabled to relieve the itching of senility by influencing the metabolism, especially of the glands of internal secretion and the activity of the skin. Roentgen irradiation might also unfold an effect in this direction.

However, in my practice as a dermatologist, I have seen numerous cases in which no success was achieved with the methods described. It became apparent to me that although we give ample consideration to the general metabolism with the application of these methods, we nevertheless neglect the chemical constitution of the organ and the changes which appear in senescence. As my own experiments have shown, the vital activity of the skin is dependent upon the chemical structure of the tissue and changes with displacements which take place in it.

It has been shown that all the organs of the body become deficient in silicic acid with increasing age (H. Schulz). The reason for this is still undetermined; perhaps the ability of transforming the silicic acid into a soluble, resorbable form is lost in senility. The silicic acid is an important element in the organism; the elasticity and the firmness of the tissues is attributed to their content of silicic acid. As the result of my experiences regarding the importance of an undisturbed balance of the mineral metabolism of the skin, I have come to the conclusion that in the treatment of the senile change of an organ more attention must be paid to its chemical constitution and that a well known error must be corrected in every case. Inasmuch as the oral administration of substances rich in silicic acid did not produce satisfactory results, about six months ago I began with the intravenous silicic acid therapy, after this proved to be harmless in arteriosclerosis, stenocardia and other diseases (L. Scheffler, A. Sartory, P. Pelissier and A. Kühn). I injected natrium silicicum purissimum in one per cent. solution intravenously. I began with 0.5 c.c. as the first injection, repeated this treatment every second to third day and increased it to one c.c., at the most to two c.c. per injection. Up to the present time, I have never given more than a total of 0.1 gram of natrium silicicum in six to ten injections. This treatment is connected with no inconveniences and has proved itself entirely harmless. It is only necessary that the injections be unquestionably made directly into the veins, as the solution produces pains in the tissue. I have seen cures in the short time of a few weeks in numerous cases of senile pruritus, even in those cases in which no success could be achieved with the methods of treatment previously mentioned.

My observations point the way to a new hopeful treatment of senile pruritus; they also indicate that at least a part of the cases of senile itching must be traced to a deficiency of silicic acid, and they show that we must pay more attention to the chemical constitution of the tissues than heretofore in order to achieve complete success with our therapy.

Yeast Therapy and Uric Acid Excretion.—Arthus H. Smith, *et al.*, (*Journal of Laboratory and Clinical Medicine*, May, 1922) reports experiments on four persons who took two, three and five times the commonly recommended therapeutic dose of live baker's yeast, eaten before meals, as recommended in the advertisements. There was no increase in the uric acid excretion following this over the level attained on a low purin diet.

Treatment of Pernicious Anemia.— Louis Henry Hempelmann (*Medical Clinics of North America*, July, 1922) believes that repeated transfusions of blood produce a marked improvement in the condition of the patient and more frequent remissions than any other method of treatment. Splenectomy offers about the same benefits. Focal infections (gallbladder and appendix) should be sought and removed if present. In spite of the more frequent occurrence of reactions with the citrate method of transfusion, it is still the method of choice. If the blood of one donor produces a reaction, another donor should be used the next time and the bloods should be carefully grouped by the method of Moss. The severity of the reaction may be reduced and the reaction may sometimes be prevented by the administration of one quarter grain of morphine with one one hundred and fiftieth grain of atropine during or before the transfusion. The frequency of the transfusion is determined by frequent blood counts and a decided downward trend of the count and also by the subjective feelings of the patient. As many as seventy-four transfusions (about nine gallons of blood) have been given to one patient. The signs of incompatibility of the donor's blood are restlessness, intense backache, vomiting, and collapse after the passage of fifteen to twenty-five c. c. of blood and subsequent hematuria. The transfusion should be stopped immediately with the first untoward symptoms and restoratives should be given at once. The first fifty c. c. of any transfusion should, therefore, be given very slowly. Five to six hundred c. c. of blood may be given at each transfusion.

Blood Serum in Pernicious Anemia.—E. M. Brockbank (*British Medical Journal,* July 22, 1922) states that the serum of pernicious anemia is always definitely yellow and that all other anemias show a nearly colorless serum. The color of the serum can be easily determined by placing two or three drops in a small glass bulb. The serum of pernicious anemia shows the oxyhemoglobin absorption band in the great majority of cases and can be easily seen with a pocket spectroscope; it occurs in no other form of anemia. European observers have found hematin in the serum of some cases of pernicious anemia and they believe that bilirubin gives rise to the yellow color. There may be some free oxyhemoglobin in the plasma of the circulating blood in pernicious anemia. Judging from the serum, there may be at least two varieties of pernicious anemia. The blood platelets are generally very scanty or absent in this disease, but when present, they are a sign of potential regeneration of the red blood cells of the bone marrow.

A remarkable improvement in pernicious anemia generally occurs for a longer or shorter time following the administration of liquor arsenicalis in graduated doses, beginning with four minims three times a day after meals and increasing the dose by one minim every forty-eight hours until doses of eight minims are being taken; the doses are then gradually decreased in the same manner until the original four minims are again being taken. The treatment is then interrupted for a week after forty-eight hours and this course of treatment is repeated for months. Bed rest and fresh air are essential. If cardiac failure is present, 1/240 grain digitoxin is given daily.

Proceedings of Societies

WESTERN SURGICAL ASSOCIATION.

Thirty-Second Annual Meeting, held at Minneapolis, Minnesota, December 8 and 9, 1922.

The President, Dr. Miles F. Porter, of Indianapolis, Ind., in the Chair.

Closure of Chronic Empyema Cavities by the Use of Strong Dakin's Solution and Gentian Violet.—Dr. W. D. Gatch, of Indianapolis, Ind., stated that in seventeen cases of chronic empyema he had succeeded in closing the cavities in fourteen by the use of the socalled chemical method. Two patients had died, but neither from causes in any way connected with the treatment. One patient, with tuberculosis, still had a small sinus, but was able to work and earn a living. The other patients were well, at work, and practically without deformity. The treatment employed had been demonstrated to be devoid of danger, and was easily carried out. The strong Dakin's solution rapidly sterilized the empyema cavity and destroyed its thick wall at a rate which was not too rapid for safety. It also probably opened up pockets of pus not draining freely into the main cavity. Bronchial fistulæ would close practically always when the empyema cavity with which they communicated was completely drained. Cavities infected with tuberculosis could not be irrigated with Dakin's solution unless they had greatly thickened walls. Aqueous solutions of gentian violet could be used to destroy the gram positive organisms in these cavities. Empyema cavities could be sterilized and closed, and would be obliterated after a time. In such cases the thickened pleura would be completely absorbed. Reinfection did not necessarily require the reestablishment of drainage.

Surgical Significance of Mesenteric Lymphadenitis.—Dr. Leonard Freeman, of Denver, Colo., said that mesenteric lymphadenitis was a common disease of children and young adults, which had received too little attention from surgeons. It was characterized by enlargement of numerous lymph nodes, usually small and soft, the infecting agent being, in many instances, the tubercle bacillus, presumably of the bovine type. The most prominent symptoms were: moderate pain, tenderness and rigidity, mostly in the right lower quadrant of the abdomen, often accompanied by slight fever, headache, occasional colic, various gastrointestinal symptoms, and loss of weight and energy. The disease was nearly always confused with appendicitis. Because surgeons were unfamiliar with the trouble, it was seldom recognized during operations. It had a strong tendency toward recovery, at least symptomatically, following laparotomy.

A New Pyeloureteral Plastic Operation for Hydronephrosis.—Dr. Arnold Schwyzer, of St. Paul, Minn., stated that the essential points of the method used in the series of cases reported were: First, the mucosa was not sutured, but brought into exact apposition. This reduced the danger of formation of concretion. In the Fenger operation which followed the pyloroplasty principle, the parts had a great tendency to pucker and separate after the catgut had given away. Unless the two ends of the linear incision remained in good apposition, there occurred a fistula with irregular wound healing. Second, and more important, the slack and fold, which were unavoidably produced by sliding the flap downward to the end of the slit in the ureter, were taken care of at the upper end of the pelvic incisions, and the ureteropelvic junction neither kinked nor puckered.

Two of the cases were closely related in their anatomical pathology, i. e., in the strictured and sharply kinked ureteral opening. Both were combined with a certain degree of infection, the first one showing a large deposit of pus in the urine, the second having considerable rise of temperature. Nevertheless, both patients were now in good health, six and a half and three and a half years after the operation. It was, therefore, permissible to try conservative measures in hydronephrosis, even in the face of a moderate infection, provided this infection had not brought on marked and lasting anatomical changes.

Pneumoventricle Cerebri Following Fracture of the Skull.—Dr. Frank R. Teachenor, of Kansas City, Mo., said that as the presence of air in the cranial cavity or ventricles did not in itself cause any deleterious effects, treatment should be directed against its most common complications: 1, meningitis; 2, intracranial compression; 3, its tendency in intracranial aerocele to the formation of cysts, by replacement of the absorbed air with fluid. Aseptic and antiseptic treatment of the wound was of prime importance. Air in the ventricles was quite rapidly absorbed and in the absence of indication for operative measures for the reduction of intracranial pressure might be ignored. In the cases of intracranial aerocele the air seemed to be absorbed more slowly, and on account of its tendency toward cyst formation, should be aspirated or drained. Drainage would also tend to lessen the danger of meningitis. The drainage or aspiration, if done, should be done early. The accompanying skull fracture and brain injury would usually indicate the type of treatment to be employed. Pneumoventricle cerebri, and especially intracranial aerocele, probably occurred more frequently than the literature indicated.

Endothelioma of the Cheek.—Dr. Edmund A. Babler, of St. Louis, stated that these tumors were very hard to classify, and, in many instances, it was a matter of opinion as to just where they should be placed. They were looked upon by some as intermediate between the sarcomata, lymphangiosarcoma, hemangiosarcomata, and the new growths of epithelial origin. They were all of mesoblastic origin, however, and belonged in the broad group of sarcomata. The case reported exemplified the fact that a fairly large sized tumor of endothelial origin might present itself in the cheek without involving the skin or mucosa of the cheek. The lymph glands of the neck become involved fairly early and quite extensively. The growth became sufficiently large as to interfere with mastication and speech.

Cancer and Benign Growths of the Female Breast.—Dr. Donald Macrae, Jr., of Council Bluffs, Iowa, said that cancer of the breast must be attacked early to insure a reasonable assurance of a cure, but how? He placed himself on record as being against the use of radium, x ray, cancer paste, or any other means except the knife. The earlier the cancer was removed by radical surgery, the greater the hope of permanent cure. Preoperative diagnosis in early cancer of the breast was usually easy. However, one must never be absolutely sure. Gummata were uncommon, but where any question existed, a Wassermann should be taken. Chancre of the nipple must be eliminated as well as tuberculous conditions and lipomata. Retraction of the nipple and glandular involvement were late manifestations, as a rule.

A movable tumor within the mammary gland was probably not malignant. He was not familiar with any other sign or symptom more positive. Surgeons and pathologists should do teamwork on all breast problems. Macroscopic examination after removal in the hands of experienced men was usually followed by a correct diagnosis. However, this examination alone should not satisfy the average surgeon. The experienced pathologist should be on hand to make frozen sections for immediate determination. A good surgeon with a poor pathologist should never attempt removal of questionable neoplasms from the human breast.

Appendicitis; an Analysis.—Dr. Edmund D. Clark, of Indianapolis, Ind., stated that in cases where there was no doubt of the diagnosis an immediate operation should be made. If this rule was followed there would be few deaths, and many of the complications common to the disease would be avoided. He believed that the appendix should be removed in suppurative cases, provided it was easy to locate and deliver. Where much trouble was encountered he drained, and removed the appendix at a later date. In his series he removed the appendix in ninety-two cases and allowed it to remain in thirteen. In all cases of chronic appendicitis where there was suspicion of trouble in the gallbladder, the stomach, or in the kidneys, the incision should be made high and large enough to examine these structures. Where he suspected trouble in the pelvis, he made the incision lower. He always used a right rectus incision. It was his practice to invert the stump of the appendix if there was not too much edema of the cecal wall. If it would not hold a stitch he tied it off and dropped it back into the abdomen. He did not remove the deep tension sutures for eleven days for fear the wound might open under some unusual strain.

Appendicitis in Women.—Dr. A. W. Abbott, of Minneapolis, Minn., said that an investigation was made to see how often pelvic peritonitis existed after appendicitis in women. The study was complex because of the necessity of eliminating all those diseases, operations, and traumatisms that might produce even a mild appendicitis. In over one thousand cases that probably might meet these requirements, only forty-two were found that were absolutely representative. Data were secured as to the relation of appendicitis to pregnancy, in addition to the pathology of the pelvis. Gross and microscopic examinations in all these cases showed the effects of inflammation. Of the forty-two cases, in ninety per cent. there were pelvic adhesions of varying extent. Comparatively little disease was found in the tubes and ovaries beyond adhesions; thirty-five were in married women and seven were single; twenty-three per cent. of the married women had children after appendicitis; seventy-seven per cent. had no children after appendicitis. Of eighteen women fertile before appendicitis, only one became pregnant after; ten had no children either before or after appendicitis; seven had no children before appendicitis, but became pregnant afterward, but these had appendicitis early in childhood.

The Significance of Rightsided Abdominal Pain.—Dr. Robert C. Coffey, of Portland, Ore., said that the chain of pathological conditions that could develop as a result of rightsided ptosis or nonfixation of the right colon might be represented as follows: Nonfixation of the cecum and ascending colon; high fixation of the appendix and its mesentery well up under the liver; fixation of the hepatic flexure to the front surface of the kidney with acquired membranous development to strengthen the support; acquired membranes extending from the parietal peritoneum across to the mobile colon; acquired membranes along the under surface of the first part of the transverse mesocolon, for the extra support of this part of the colon; one band extending along the omentum from the colon to the under surface of the gallbladder, another extending from the colon across the duodenum, making extra fixation; a midline ptosis probably due to dilatation of the stomach secondary to dilatation of the duodenum, which was produced by duodenal arterial mesenteric ileus. These conditions, when taken with the history of the case, made a complete clinical and pathological picture of rightsided ptosis and offered a perfect explanation of the significance of marked rightsided abdominal pain which was not based upon an organic lesion.

Radical Operations on the Stomach.—Dr. William J. Mayo, of Rochester, Minn., after reviewing the various methods of radical operations on the stomach for cancer, with special relation to their applicability in cases of ulcer, discussed partial gastrectomy of the Billroth I type, that is, direct union between the gastric stump and the duodenum, and pointed out that the lesser curvature was the key of the anatomical lock which prevented mobilization of the stomach so necessary for operations of the partial gastrectomy type. He showed that if the gastric artery was tied early and the gastrohepatic omentum was separated from the liver, that by traction on the distal stump of the gastric artery the fat, the glands, and the unyielding structures of the lesser curvature of the stomach could be dissected out, the arteries being tied as they were encountered. This enables the lesser curvature to be elongated remarkably, and in the majority of cases in which the carcinomatous growth or ulcer was situated in the pyloric end or in the lesser curvature distal to the incisura, would permit excision of the diseased portion of the stomach, to be followed by direct union between the stomach and the duodenum. When the cut end of the stomach was more than twice the diameter of the cut end of the duodenum, it should be narrowed by proper suturing of the lesser curvature. The gastroduodenal union was accomplished by taking two stitches on the gastric side to one on the duodenal side, which produced a remarkably smooth anastomosis. Following the gastroduodenal union, the stomach was caught by two catgut sutures placed in the anterior wall sufficiently proximal to the anastomosis, so that when it was attached to the suspensory ligament of the liver it would carry the gastroduodenal anastomosis to the right of the spine, taking the tension from the suture line and improving gastric drainage.

Acute (Puerperal) Inversion of the Uterus.—Dr. Edward Evans, of La Crosse, Wis., said that in the case forming the basis of this paper there had been inversion four hours after manual delivery of the placenta, the patient having been brought to the hospital twenty-eight hours after inversion. On entrance she was anemic, had a temperature of 100.6° rectal, pulse 120. There was complete inversion of the uterus; no cervical ring could be found in the vagina. The uterus was reduced by laparotomy, stretching the cervical ring with the fingers and an assistant inverting the uterus with the hand in the vagina. The patient recovered after a stormy convalescence, during which she had phlebitis in each leg.

Cholecystectomy Without Drainage.—Dr. W. A. Coventry, of Duluth, Minn., said that there were only four deaths in his entire series, and all were drainage cases, but this was largely a coincidence. The first occurred on the third day from a streptococcus infection, proved by autopsy. There was absolutely no leak from the bile passages, nor from the appendix (which was removed at the same time), but it was proved that the infection came from an outside source. Acute dilatation of the stomach occurred forty-eight hours after operation, massive collapse of the lung on the fifth day, and peritonitis and anuria on the eighth day. In practically every case of cholecystectomy one could, if the technic was properly carried out, close the gallbladder incision without drainage. If one did, he felt certain that the postoperative pain, especially passing up into the shoulder blade and scapula, the postoperative nausea and vomiting, postoperative temperature, postoperative tympany, and finally the end result, would be much smoother, more pleasant to the patient and to the surgeon, and far more gratifying in all respects.

Pyelography in Abdominal Diagnosis.—Dr. Daniel N. Eisendrath, of Chicago, spoke of the necessity of a thorough examination of the upper urinary tract in the differential diagnosis of cases presenting symptoms of a subacute or chronic character. Pyelography and ureterography were of greater value than the employment of the shadowgraph catheter alone. In cases where pain was the principal symptom, a pyelogram or ureterogram would at times reveal the presence of changes in the pelvic outline as the result of pyelitis or ureteritis, or of a hydronephrosis or hydroureter due to obstruction, such as kinking from an abnormally movable kidney, calculus, stricture or an abnormal vessel to the lower pole. The differentiation of shadows due to gallstones from those due to renal calculi had been greatly aided by pyelography and a number of slides were shown to illustrate the application of the method.

Perforated Gastric and Duodenal Ulcer.—Dr. A. C. Stokes, of Omaha, Neb., said that the treatment most in vogue was simple closure of the ulcer with gastroenterostomy reserved for pyloric stenosis, perigastric adhesions, and large indurating ulcers. This should be attempted only at the time of the perforation when the patient was in the best of condition, and within twelve hours after the perforation. Simple closure of a perforated gastric or duodenal ulcer cured the ulcer in about eighty per cent. of the cases. The mortality following operation for perforated gastric ulcer increased in direct proportion to the number of hours following the perforation at which the operation was performed. All operations for perforated gastric or duodenal ulcer should be followed by proper medical treatment for considerable periods of time after the operation.

Open Treatment of Apparently Hopeless Cases of Cancer in Conjunction with Radium and X Ray.—Dr. Emil G. Beck, of Chicago, reviewed his work of the past eight years in using this method, which consisted in the removal of all cancerous tissue consistent with safety to the patient's life, leaving the wound widely open and treating the open cancer field with radium and x ray. He reported and demonstrated a number of cases, some belonging to the hundred per cent. mortality group, without recurrence from three to five years.

The essential requirements for successful treatment were: 1. Cooperation with a thoroughly competent radiologist and pathologist. 2. Personal supervision of each case, including the dressings and constant watching of the effects of radioactive substances. He discussed the morphological and biological changes in normal cells and cancer cells after radiation. The factors which determined the tissue changes were: 1. Dose of radium or x ray at source. 2. The distance of the radioactive substance, or the anode from the body. 3. The length of time of exposure. 4. The thickness of the intervening tissues. A small amount of radiation had a tendency to accelerate the growth of tissues, and caused proliferation of the cells. Larger doses would paralyze the reproductive power of the cells, and thus retard or entirely inhibit the growth without actually destroying the life of the cell. Massive doses would destroy the life of the cell. It was disintegrated and the end products were absorbed in the body and eliminated through the excretory organs. This applied to all living cells, but some cells were more resistant than others to radioactive application. The author offered an interesting theory for the radiosensibility of cancer cells. He compared the mass of cancer cells to an alienated, detached, and lawless community of cells which had two functions, nutrition and reproduction. They appropriated nourishment at the expense of the whole human body and grew without definite arrangement of structure in an unorganized manner. They did not give any counterservice in return for the nutriment they received. The cancer cells were detached from the central nervous system and, therefore, injury to them was not under the protection of them; they might be injured more easily by radioactive substances, or any other agent, such as heat or even the actual cautery, than the normal body cells which enjoyed the protection of the organism.

(*To be concluded.*)

Abstracts from Current Literature

CLINICAL MEDICINE.

Sugar Metabolism.—Alfred Gigon (*Schweizerische medizinische Wochenschrift,* December 30, 1922) found that the power of rotation of solutions of glucose that are mixed with ammonium carbonate and ammonium sulphate, ammonium chloride and calcium hydroxide is rapidly reduced. Sugar resorbed in the intestine is demonstrable in the blood only in a low percentage after a few minutes. The author assumes that the greatest part of the sugar is bound by the nitrogenous substances in the blood and that it is not transformed into glycogen during its first passage through the liver, but only after it has circulated through the body and has returned to the liver through the hepatic artery. The blood sugar may be an important factor chiefly in the normal albumin metabolism and the changes in the albumin metabolism may be a criterion of the variations of the blood sugar, as, for example, in the hyperglycemia and in the dextrose test after fasting for twenty-four hours or after work.

Further Clinical Experience With Insulin in Treatment of Diabetes Mellitus.—F. G. Banting, W. R. Campbell and A. A. Fletcher (*British Medical Journal,* January 6, 1923) summarize the results of their investigations as follows: 1. Under treatment with insulin in patients who are not otherwise amenable to treatment: a, glycosuria is abolished; b, ketones disappear from the urine and the blood; c, blood sugar is markedly reduced and maintained at normal levels; d, the alkali reserve and alveolar carbon dioxide of patients in acidosis and coma return to normal; e, the respiratory quotient shows evidence of increased utilization of carbohydrates; f, the cardinal symptoms of diabetes mellitus are relieved and the patients show well marked clinical improvement. 2. Insulin is a specific in the treatment of diabetic coma. 3. Certain procedures are suggested as a guide in the administration of insulin. 4. Hypoglycemic reactions in man have been studied and described. 5. Hypoglycemic reactions following insulin treatment are relieved by the administration of carbohydrates and also by the injection of epinephrine.

In order to determine what patients require insulin treatment and the requisite dose, the following general plan of investigation and treatment was adopted: The history and physical examination of each patient are investigated on admission. Patients admitted in coma or in the precomatous state are given insulin treatment immediately. For other patients, a diet, calculated on the normal basal calory requirement for that particular age, height, weight and sex is given; it should contain sufficient protein to maintain nitrogenous equilibrium and carbohydrates and fats in such proportion as to avoid the excessive formation of ketones. Fasting for a day helps to attain constancy of sugar excretion more rapidly. Patients are kept in bed for a time and then only slight exercise is allowed. Routine blood and urine examinations are done for a week or more. Those cases showing decided glycosuria and hyperglycemia, with possibly various degrees of acidosis, are selected for insulin treatment. With a preparation of insulin known to be potent and to contain about one unit to one c.c. according to the pharmacological assay, an amount is given which is calculated to be somewhat less than that required to render the urine sugar free. Insulin is administered, according to the amount required, in one, two or three doses, at or shortly before meals. Subcutaneous injection is the method of choice. Uranalyses at short intervals determine when the patient becomes sugar free, and the subsequent doses are adjusted to keep the patient in this condition. The food should be prepared in an inviting manner. Complete records should be made of twenty-four-hour specimens of urine, which are to be examined qualitatively and quantitatively for sugar, acetone, diacetic acid, and the total nitrogen and the routine tests for volume, specific gravity, albumin and the character of the sediment should also be made. All patients are benefitted by this treatment.

Glucose Tolerance in Chronic Arthritis and Allied Conditions.—G. L. Kerr Pringle and S. Miller (*Lancet,* January 27, 1923) concludes: 1. That a lowered glucose tolerance is present in a large proportion of cases of arthritis and muscular fibrositis, which lowered tolerance is specially marked in the great majority of the severe infective cases, as well as in the cases of periarticular fibrositis and muscular fibrositis (2). That the degree of intolerance is roughly proportional to the activity of the arthritic process. 3. That the glucose toleration reaction tends to return to normal with convalescence and recovery, which return to normal, in most cases, is most rapid when the infective foci have been removed. 4. That the estimation of glucose tolerance, taken in conjunction with the other clinical signs and symptoms, is of assistance in classification as well as in the prognosis of cases of arthritis. 5. That in cases with a markedly lowered glucose tolerance, and in which the focus of infection can not be found and removed, the prognosis is bad.

Interpretation of Blood Sugar Estimations That Are Near the Normal.—Henry J. John (*Journal of Laboratory and Clinical Medicine,* December, 1922) described six cases in which the blood sugar value was from 123 to 161 mg. to 100 c. c., with glycosuria in one case. In all these patients the blood sugar was near normal, but when a glucose tolerance test was made, a definite diabetic curve was obtained. In discussing these cases the author points out that blood sugar levels which are near the normal should not be interpreted as such until it is known under what conditions the blood was obtained (whether the patient has been on a diet, etc.), and until it has been determined by a glucose tolerance test that the slight rise is of nondiabetic origin. In borderline cases with a diabetic trend a simple restriction of carbohydrates will usually carry the patient comfortably through life, but if the case is allowed to go on without dietary supervision, it will reach the stage when a marked restriction of proteins and total calories as well as carbohydrates is necessary.

Diastase in Blood and Urine in Diabetes Mellitus.—Estimations of diastase simultaneously in blood and urine made by G. A. Harrison and R. D. Lawrence (*British Medical Journal,* February 24, 1923) in fifty-five diabetics and a large number of controls support the theory that the presence of amylase is more or less accidental and of little value in the diagnosis, prognosis, or treatment of diabetes mellitus.

Pancreatic Diabetes in the Dog.—John R. Murlin, Benjamin Kramer and J. E. Sweet (*Journal of Metabolic Research,* July, 1922) report experiments on the administration of pancreatic extracts to depancreatized dogs, done from 1913 to 1916, which supply additional proof of the presence in pancreatic tissue of a substance capable of restoring to the diabetic animal the ability to utilize glucose. This work thus confirms the recently reported studies of Banting and Best.

Influence of Benzyl Benzoate Upon Nitrogenous Metabolism.—George T. Pack and Frank P. Underhill (*Journal of Metabolic Research,* July, 1922) believe as a result of their experimental work on dogs that the therapeutic dose of benzyl benzoate for human beings is probably insufficient to disturb the normal nitrogenous metabolism. Larger doses, above 0.5 c. c. to the kilogram of body weight, cause an increase in protein catabolism in dogs. The titratable acidity and total phosphorus excretion in the urine are augmented, the tital nitrogen output is increased, a marked creatinuria occurs, and conjugated glycuronates appear in the urine. Creatinine metabolism is not modified.

Studies in Carbohydrate Metabolism.—I. Some Comparisons of Blood Sugar Concentrations in Venous Blood and in Finger Blood.—G. L. Foster (*Journal of Biological Chemistry,* February, 1923), compared the concentration of blood sugar in venous blood and in finger blood of healthy students after the ingestion of various sugars, with the following results. In the fasting condition the sugar concentrations of finger blood and venous blood are practically the same. After the ingestion of glucose, the sugar in the finger blood rises to much higher levels than in the venous blood. After fructose the rise in the finger blood is much less than after the ingestion of glucose, while the rise in venous blood is slight and often entirely missing. Galactose showed much higher levels of hyperglycemia and a close correspondence of finger and venous blood throughout the curve. After starch curves like those following glucose were obtained. No change was found after the ingestion of agaragar.

The Action of Phosphoric Acid Ions Upon the Blood and Urine Sugar in Man.—H. Elias and St. Weiss (*Wiener Archiv für Innere Medizin,* April 5, 1922) show that intravenous injections of hypertonic monosodium and bisodium phosphate solutions, with few exceptions, diminish the diabetic and alimentary increased blood sugar, but not the normal blood sugar. Every one of these blood sugar reductions is associated with and followed by a reduction of sugar excretion, if such exists; this reduction of the blood sugar lasts from two to four hours and that of the urine sugar lasts up to three days. The three grades of diabetes can not be differentiated by the injection of phosphates. The action of the phosphates seems to affect the intermediary metabolism directly and the kidneys indirectly. It is associated with the phosphoric acid ion; the alkaline bisodium phosphate is three times as effective as the acid monosodium phosphate. The reduction of the phosphorus content in diabetic serum cannot explain this phenomenon: the phosphorus values in diabetic and normal serum are equal. There is no reason for believing that a formation of dextrose diphosphoric acid is the cause of the reduction of the blood sugar level, nor can an oxidizing glycolysis be demonstrated in blood. The sugar actually disappears from the blood as a result of the action of the phosphoric acid, either by combustion processes otherwise induced, or by the storage of a carbohydrate or a carbohydrate phosphoric acid in the tissues, as explained by the varying permeability of the muscle cell membranes.

Studies of the Slight Glycosurias.—J. E. Holst (*Acta Medica Scandinavica,* November 29, 1922) describes seventeen cases of light glycosuria, that is, glycosuria without diabetic symptoms. In these the amount of blood sugar was measured on an empty stomach, the alimentary variation, and the amount of blood sugar causing glycosuria. Hagedorn's micromethod was used in these experiments and also Hagedorn's technic used for studying the blood sugar curve after ingestion of one grain of glucose in ten grams of water to the kilogram of body weight. The cases were divided into three main groups, the diabetic, the renal, and a transition type, of which seven cases were reported. Besides these there were some cases of temporary glycosuria in which the functional tests gave normal results and in which no metabolic or renal anomalies could be demonstrated. The experiments confirmed the theory that renal glycosurias are of benign character. This was also true of the transition types. The diabetic type of cyclic glycosuria with proper treatment offers a good prognosis. As to whether these cases show a progressive tendency when not treated has not been definitely confirmed.

Use of a High Fat Diet in the Treatment of Diabetes Mellitus.—While the use of fasting and undernutrition has been attended by a great improvement in the treatment of diabetes, especially in its severer forms, L. H. Newburgh (*Medical Clinics of North America,* March, 1923) believes that certain theoretical considerations suggest that moderate restrictions of calories during the period of desugarization will accomplish as much as complete fasting, and that a maintenance diet will be just as capable of keeping the patient sugar free and of preventing or delaying downward progress as will undernutrition. Since fasting and prolonged undernutrition inevitably lead to incapacity, it is eminently worth while to determine by actual trial whether a dietetic regimen that allows sufficient calories to avoid this evil will control the disease itself as effectively as the more rigorous plan. In order to supply more calories without increasing the glucose equivalent of the diet, it is necessary to feed the patient a diet relatively much higher in fat and poorer in protein has been customary in the past. The use of such high fat diets can be justified only when it has been proved that the additional fat does not increase the liability to acidosis. In two hundred consecutive cases of diabetes mellitus the author has been enabled to show that high fat, low protein and low carbohydrate diet not only causes no acidosis, but is even attended by its disappearance in those patients who were suffering from an acidosis at the beginning of treatment.

Further Experiments With High Fat Diets in Diabetes.—Frederic S. Leclercq (*Journal of Metabolic Research,* July, 1922) describes three cases of severe diabetes showing the effect of increasing the diet with fat beyond the caloric tolerance. Such a procedure will cause a rise in the blood sugar, generally slow, but in the severest cases it may be rapid. The cases illustrate the well known fact that in fasting or undernutrition even emaciated patients derive their energy chiefly from body fat. It is the opinion of Leclercq and of the Physiatric Institute that the statement that severe cases of diabetes can be cleared up by high fat diets is contrary to their experience and to fact. The attempt to prevent undernutrition by giving fat or any other kind of food prevents also the benefits of undernutrition.

Glucose Tolerance Test.—Wann Langston (*Journal of Laboratory and Clinical Medicine,* February, 1922) reports a series of 235 observations on 154 patients, fifty-three of whom had proved carcinoma. From these results and a study of the literature he concludes that carbohydrate metabolism is under control of the internal secretion, and is sensitive to changes in endocrine function, and it is also disturbed by carcinomatous growth. Therefore the blood sugar tolerance test should be of value in these conditions, although the test needs further confirmation. While there is no sugar tolerance curve definitely characteristic of carcinoma, in most cases there is a certain type of curve which is found in comparatively few other conditions, including tuberculosis, diabetes mellitus and hyperthyroidism. In suspected carcinoma of the bile tract area complicated by jaundice, the test is of no value.

Blood Picture in Gout; With Some Notes on Tophi.—J. M. H. Munro (*Lancet,* May 13, 1922) found the blood counts strikingly similar in several respects to those obtained in nongouty multiarticular arthritis. The erythrocytes were over and under one hundred per cent. in about equal proportions, but the hemoglobin was deficient in all cases; hemoglobinemia is equally characteristic of gouty and nongouty polyarthritis if chronic. The leucocytosis varies in gout in the course of active joint involvements. Tophi may show either a milky fluid content or chalky concretions, or a sanguineous fluid. Neither will invariably show crystals, nor are the urates invariably crystalline in tophi. The chalky concretions may contain no urates but principally calcium phosphate (wrongly called chalky gout).

Serological Classification of the Staphylococci.—T. G. M. Hine (*Lancet,* December 30, 1922) concludes that there are two main groups of staphylococci: those being pyogenic and almost always forming acid with mannit, and those resembling the socalled Staphylococcus epidermis albus, usually failing to make acid in mannit broth and generally forming white colonies. The first group contains at least three serological types, of which the first type represents 90 per cent. of cases. The second group contains two serological types, the second of which is not so common as the first and appears also to have some pathogenic properties. The agglutination tests of the staphylococci, while affording some indication of serological types, are insufficient without absorption of agglutination tests to determine the serological position of many individuals.

Effects of Various Foods, Food Factors, and Chemical Agents Upon the Resistance of Animals to Acetonitrile.—Masataro Miura (*Journal of Laboratory and Clinical Medicine,* February, 1922) used standardized, synthetic foods, the nutritional significance of every factor of which was known, so that the constituents could be varied at will, while the composition of the food was kept under exact control. The results of this work show that only in the cases of underfeeding, of feeding with iodine as the solid mineral, of feeding with oat starch, and possibly of diets high in fats, was any alteration in the resistance to acetonitrile obtained. It therefore appears that the susceptibility of mice to poisoning with acetonitrile is not easily affected by changes, either of quantity or quality, in the dietary composition, and it is suggested that this may serve to emphasize the factor of safety possessed by the organism in its response to alterations of the diet.

Occurrence of Anemia in Rats on Deficient Diets.—William M. Happ (*Bulletin of the Johns Hopkins Hospital,* May, 1922) found that a diet deficient in iron alone does not produce anemia in the rat in the first generation, nor do diets consisting solely of cow's milk or milk and bread. On these diets slight anemia may occur in rats of the second generation. Diets deficient in an organic substance contained in codliver oil and to a less extent in butter fat, and which also have a low calcium high phosphorus ratio, producing ricketlike changes in the rat, cause anemia in some animals. Those of the second generation may also become anemic on this diet, the anemia being associated with evidences of increased hematopoietic activity, and frequently an enlargement of the spleen, resembling the anemias associated with rickets in human beings. Diets which produce severe rickets with great regularity, those low in the organic substance contained in codliver oil, and low in phosphorus with a normal calcium content, do not cause anemia; nor do diets deficient in fat soluble A or water soluble B, although they cause severe nutritional disturbances. Diets which were so deficient in water soluble B as to produce polyneuritis diminish leucopoietic activity and cause a severe leucopenia, with a shift to the right in the Arneth formula.

A Septic Form of Stomatitis.—Karl Kundratitz (*Wiener klinische Wochenschrift,* July 13, 1922) reports a case of a true primary, membranous stomatitis with septic symptoms in a boy twelve years old. This case closely resembles the disease picture described by Widowitz, with the exception of the absence of the septic exanthem and empyema. The author believes that the absence of these two symptoms is traceable to the greater power of resistance of the older child.

INFECTIOUS DISEASES.

Etiology of Scarlet Fever.—R. W. Pryer (*Journal of Laboratory and Clinical Medicine,* July, 1922) states that the organism which had previously been reported by him as being found only in scarlet fever shows several varieties. Under certain conditions one of these was somewhat similar in its morphology to Bacillus diphtheriæ and may be a toxin producer. Diphtheria antitoxin protects against this culture, providing the antitoxin is given some time before the injection of the culture. Pryer gives a preliminary report of the results obtained by culturing patients sick with scarlet fever, which he believes justifies the tentative conclusion that this variable organism is the cause of scarlet fever.

Fourth Disease or Para-Scarlet?—K. Simpson (*Lancet,* August 19, 1922) had occasion to observe a series of cases resembling scarlet fever, which occurred in a diphtheria ward. The onset of these cases resembled scarlatina in acuteness, except that vomiting occurred only once coincidently with the onset, which was marked by malaise, headache and slight sore throat, a temperature between 100 and 101° F., and a pulse ranging between 90 and 100 a minute. The headache was a pronounced symptom. The sore throat was not pronounced and felt rather like a dull pain (congestion of the fauces). The adenitis was slight and usually limited to the submaxillary glands. There was no suffusion of the conjunctiva, no stiffness of the neck and no marked adenitis. Coincidently with the onset, the rash appeared during the first day of illness upon the sides of the neck, extending upward toward the cheeks; the circumoral pallor was not noticeable. The rash lasted an average of about twelve hours and was more uniform and erythematous than in scarlatina; punctation was slight. The color of the rash was a bright rosy red. The parts of the body involved were the abdomen, chest and upper extremities, sparing the lower extremities. The tongue was covered with a thick, creamy white fur, which gradually cleaned up but the tongue did not show the typical raspberry stage. Desquamation occurred on the third or fourth day on the lobes of the ears and upper sides of the neck, was of the pinhole type and was confined to these areas; toward the middle of the second week, a scarlatiniform peeling was noted on the hands and feet, but nowhere else. The convalescence was uneventful and showed no complications. The evidence seems to point in favor, not of a separate fourth exanthem, but rather in favor of a mild but distinct type of scarlet fever, mild in form and distinct, in view of the immunity against subsequent infection with scarlet fever.

Intermittent Treatment of Malaria With Quinine.—Karl Glaessner (*Wiener Archiv für Innere Medizin,* October 15, 1922) reports gratifying results in a series of seventy-seven cases of malaria, in which quinine was administered according to the method of Ochsner. The bowel is emptied with thirty grams of castor oil on the night before the treatment is begun and for twelve days all meat is forbidden, only a soft and fluid diet (preferably lactovegetarian) being allowed. On the two days following the purge, the patient is given 0.15 gram quinine by mouth every two hours, day and night, simultaneously with about 0.25 litre of a hot drink. This course of treatment is then followed by an interval of eight days, when the same course of treatment is repeated.

Infectious Mononucleosis (Glandular Fever).—Warfield T. Longcope (*American Journal of the Medical Sciences,* December, 1922) describes ten cases of this disease and discusses its relation to glandular fever. The uniform character, and the association of an enlargement of the lymph nodes with a striking increase of mononuclear cells of abnormal type in the blood serve to differentiate this condition from other acute infectious diseases. It resembles acute leucemia but may be differentiated by many characteristics. It is of short duration and recovery is the rule.

Immunity Studies of Rocky Mountain Spotted Fever.—Hideyo Noguchi (*Journal of Experimental Medicine,* March, 1923) states that the early administration of immune rabbit serum in guineapigs inoculated with the virus of Rocky Mountain Spotted Fever will suppress the infection if it is given within the period of incubation, the effect being proportionately greater the earlier the serum is administered. If it is given after the onset of the disease almost no beneficial effect is observed. In view of the comparative susceptibility of man and the guineapig, Noguchi recommends that in every instance when the bite of a tick gives rise to the suspicion of a possible infection with spotted fever, or when a person accidentally inoculates himself with the virus, about 0.2 c. c. of the serum to the kilo of body weight (or 0.1 c. c. to the pound) be administered immediately, preferably by intravenous injection. For the average adult about sixteen c. c. should be given. The serum is easily produced in rabbits, and probably will remain active for a year or longer at refrigerator temperature.

The Medical Fakirs of Athens and the Sexual Problems of Babylon in the Days of Herodotus

By JONATHAN WRIGHT, M.D.,
Pleasantville, N. Y.

When the circus comes to town the impression made on its citizenship is not always confined to the juvenile members of the population, but chiefly on the juvenile minded. The childhood of the race becomes prominent in the throngs that line the route of the procession. We can not but conclude from the study of the pages of history, reinforced by prehistoric evidence, that in the childhood of our civilization this juvenile minded portion of humanity had a wider expansion and received more deeply extended impressions from the innumerable processions, temporal and secular, triumphal and Bacchanal, funereal and supplicatory, patriotic and political, than has been the case for us in the more advanced nations of the earth in many hundred years. This sort of thing is an appeal to the minds of men through the emotions, moved in the crowd as they are and often leading to erroneous and harmful conclusions. It stirs the heart of man as it did that of Xerxes who fell into tears at seeing the mighty host he commanded spread out before his eyes at the Dardanelles, as it is related in the pages of Herodotus (1).

I have elsewhere in this journal (7) made some reference to snake worship at the dawn of medicine. Historically it is curious to see the snake crawling over from Africa and the Asiatic tropics into the beginning of our civilization in Europe. One of the stories (8) of the birth of Apollo surrounds the infant prophet of the soil with a variegated copper colored snake, a monstrous creature, unfamiliar to the inhabitants of Parnassus. The snake charmer and his box of snakes no doubt not only frequented the roads of ancient Greece, but the chariot tracks of the other side of the Ægean. We have some intimation from Herodotus that at times he bore a prominent part in the shows that the Athenian small boy and the rabble beneath the Acropolis gazed upon of old.

"In the Pæanian Deme there was a woman by the name of Phue about six feet high or perhaps a little less and good looking." Peisistratus dressed her up in garments suitable for the occasion and mounted her on a trim wagon and sent heralds before her to announce that Athena was much interested in leading the banished Peisistratus back to Athens. The heralds went ahead crying: "O, Athenians greet with good will Peisistratus whom Athena loves especially of all men to honor and whom she is bringing back to the Acropolis" (2). This must have been about 550 B. C. For a trick upon such worldly wise men as the Athenians Herodotus thinks this the most foolish thing he ever heard of, and fit only to play on the rudest tribes of men, but there was another procession in Herodotus's time in which we are more interested and it would have been a boon for us if he had told us of it, instead of leaving it to the tradition of later writers. How aware he was of the tendency of tradition to err, how wary he was not to put the stamp of his approval on that which did not appeal to his judgment as probable, we gather every now and then from his pages. "The Greeks say,"—"so the priests tell the story,"—"the Argives say this, but the Spartans deny it,"—"they tell it in this wise." These are phrases familiar to the lover of Herodotus. He specifically declares: "I like to tell what is generally said, but I do not care to believe in it all" (3). Yet until archeology of recent years proved him more often right in what he himself observed or stated on his own belief than not, Herodotus was held in contempt for his credulity by rigid historians whose chief asset was skepticism.

It may be that he did not realize how unsophisticated, how nearly barbarous the Athenians were in the time of Peisistratus, as compared with those in the time of Pericles. More than a hundred years separate these eras and Herodotus was perhaps ten years younger than Pericles. We would perhaps be disposed to join in the judgment of Herodotus as to the trick of Peisistratus, except that there have been since his time certain phenomena which dispose us to disbelieve less in the gullibility of men as wise, in citizens as sophisticated as the Athenians. Wisdom was rather cried up in the time of Herodotus and Hippocrates, but common sense and *sophrosyne*

Copyright, 1923, by A. R. Elliott Publishing Company.

in Athens did not always rule the roast and it has been somewhat lacking there in our day. Sophocles was more of the age of Pericles, ten years older than Herodotus, and a citizen of Athens which Herodotus was not. It is said, however, that the two were personal friends.

In Sophocles's day, in 421 B. C., the cult of Æsculapius was formally welcomed to Athens and honored with an ode by him, as a priest of a medical cult. If the god himself did not come from Epidaurus in the form of a snake to Athens as he did to Sicyon riding in a wagon driven by a Sicyonian woman (9), the priest of Æsculapius brought snakes along with him and Sophocles entertained him, if not his snakes, at his house. That is the way we would expurgate the story and we find it reasonable, with Miss Harrison (10), to believe some new point of view in medicine was then engrafted on the ideas already existent in the medicine of Athens, but according to the record it was the god Æsculapius that Sophocles received at his house as a guest, and after generations called Sophocles, by that token, "The Receiver." How much of a revolution there was in Athenian medicine it is hard to say, but the Dexion and Amynos of the inscriptions fade out after that date and Æsculapius reigns with his snakes in the temples, but Aristophanes made fun of them. So the procession which carried Æsculapius to Athens did not again throw dust in the eyes of the Athenians as Peisistratus had done, to the wonder of Herodotus.

We can readily believe here in New York, where a new healer lands at the port or comes overland to town every year, not in a procession perhaps, but heralded by the blowing of trumpets in the press, that a fakir with a box full of snakes and another full of medicines he knew how to use came to Athens and was welcomed by the high priests and their congregations. We must think of these things in terms we understand. But since for all we know he was hospitably received by the doctors of Athens, Æsculapius may have been a little late in coming from the east and when he did come and, being immortal or long lived, he was received with cordiality, but he would have been stoned if he had come in the guise of any mortal like Lister or Pasteur. And that is another way of thinking of it in terms we understand. The world is very old and the sun appears to go around it just as it did twenty-five hundred years ago and with the sun all good things, religious and intellectual, come from the east just as they did then. From Thessaly to Athens, from the Asiatic littoral to the European, the torch was passed. We have handed it on to Japan and still the world rolls around just as it did in the time of Hippocrates and Herodotus.

But Herodotus was right, the Athenian Greeks at the height of their culture would not have stood for a woman driving a snake to town in a landaulet, as they are said to have done at Sicyon, though as I have hinted, that legend, if founded on fact, must have been that of some fakir with a box of snakes going from Epidaurus elsewhere to try his luck. We begin to see plenty of them in New York since the Great War has made it the capital of the world. Aristophanes in the Plutus made all sorts of fun of the temple snakes and the people who believed in them. That may be some excuse for thinking it created considerable commotion in town when the person representing Æsculapius, with snakes in his luggage, was welcomed by Sophocles, popular dramatist, great poet, high priest, high in the affections of his countrymen, even if he was a failure in war. But the fun for the Athenians in the snake motif argues that Aristophanes used the joke because it was new—something come to town recently in 421 B. C., like the Volstead act to Broadway. The jokes added to the gaiety of the Athenian populace until they tired of them, but for all that the snakes remained behind in the temples as long as they stood. I believe there is at present as great a dearth of prohibition jokes in our select theatrical circles as of liquor on the Great White Way.

Miss Harrison seems to think there were sacred snakes in Athens before those came from Epidaurus with the priest of Æsculapius, but if the snakes were an old thing in Athens in 421 B. C., Aristophanes would never have raised a laugh at them in the Plutus. As Herodotus suggested then, it did seem ridiculous to dress up a woman known in one of the demes in Athens and bring her to the Acropolis as Athene, for Herodotus had in his mind the Athens of his day, when Aristophanes made the citizens roar with the snake jokes on the stage. The woman as Athene may have been no joke in politics a century or more earlier. They may have had medical snakes then, too, without eliciting a smile from any except the ungodly. It is likely the snakes and the medical virtues in them and the fun to be had out of them lay dormant. Early faith was a somnolence of the mind. There was a flash of it again when Sophocles wrote his ode, Sophocles pious and awe struck and quite as religious as Herodotus, but the populace was different and the playwriter had his chance. It was no sacrilege any longer to make old women on the stage scream when they touched a cold snake in the night gloom of the temple. I do not know what would happen to the writers of some of the sacrilege nowadays if they were moved back a hundred years even into the wicked New York of our great grandfathers.

Herodotus had his credulities, too, but Hippocrates had no use for snakes and he was born at Cos not far from Halicarnassus across the water, when Herodotus was a boy there of ten perhaps. When Hippocrates was about forty years old we were in the age when the Athenians laughed at snakes, but for all that they crawled around the temple wards. Side by side with Hippocratic science bloomed the absurdities and rascalities of medical charlatanry. Is it different in our day? We try to laugh down the various fake "sciences," but do we? Ridicule is considered a mighty weapon, but it is a flash in the pan that neither prevails nor endures in the face of truth or of error when supported by faith and fanaticism. Wit and ridicule are the wisdom of the foolish, sharpedged perhaps but without temper in the blade or weight in the handle. We all draw the line somewhere and Herodotus drew it at the six foot woman of the deme of Pæania as Athene; that was merely silly.

As I have said, I have contributed in these columns something to the general subject of snake worship in connection with the rise of medicine to a science, but I trust it has done no harm to linger and elaborate with some repetition and some extravagance of space the question of the attitude of cultivated Greeks toward it, with the help of Herodotus and Hippocrates, of Sophocles and Aristophanes. I do not know how one is to understand or even get an idea what medicine really was in any age unless we seek it out in the lay writings of men who have made it famous and are to us its noblest representatives. This sort of thing has to be done by approaching it from different angles, just as in a picture gallery one shifts to different positions to get new light on a great painting.

The curious phenomenon of the drift of enlightenment in the world's currents from east to west has attracted the attention of the most casual reader of history. So gradual, so devious, often so hidden, so insidious, is the march of ideas that lie at the bottom of our religion and our philosophy, our medicine, that we often rub our eyes and try to convince ourselves it is an illusion from which we suffer, seeing the sun rise every morning in the east. We are betrayed by a flower of rhetoric, is our constant precautionary thought. Rome and Athens we see invaded by Oriental influence and beyond them to the west Cimmerian darkness. It is astonishing how ignorant the ancient Athenians were even of the western end of the Mediterranean lands. The snakes, as well as Hippocratic medicine, came there from the other continents, it would seem, the good with the bad.

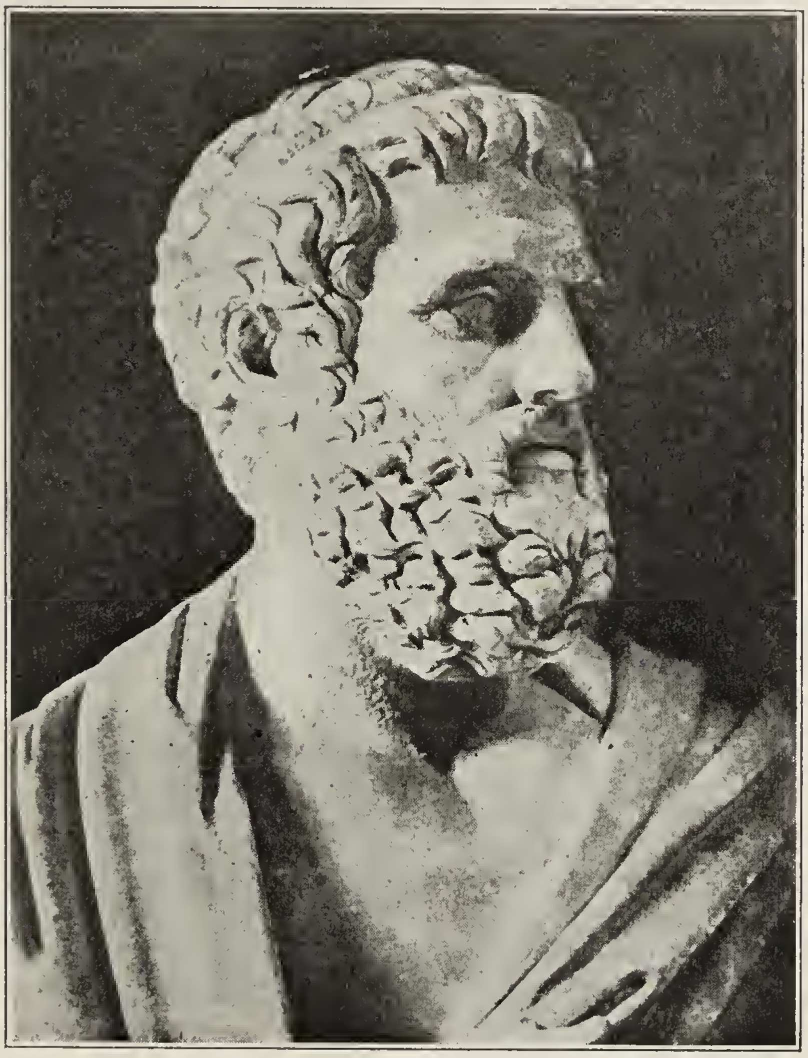

FIG. 1.—Sophocles. (From Greek and Roman Portraits by Anton Hekler.)

The problems of the ancient civilizations have been moved along the roads in the same direction, and we are wrestling with them as they did in Babylon and Susa. Cos less than Cnidus was engulfed in the Persian wave of conquest which swept up to and around the eastern shores of the Middle Sea in the century which produced Pythagoras and Solon and Æschylus. The Persian power enslaved the islands of the coast and profoundly affected their culture, and it may be doubted that it contributed considerable influence to the currents of scientific thought which began to move among the European Greeks, but the Asiatic Greeks, the islanders, became deeply infiltrated through Persian agency, not alone with the lore of Babylon and even of distinct India, but it is probable that through this roundabout channel much of Egyptian learning reached even Athens. As for the Aciatic littoral, it was through Persian imperial commingling of races and ways of thinking and the arteries of travel opened up and the science of Egypt with which it was brought in contact, that it became orientalized after the irruption of northern barbarians on the outlying fringes of Babylonian and Egyptian power, both of them long since beginning to crumble with age. Under the Persian influence, if not its direct domination, arose the Nature Philosophers, Thales, Anaximines, Anaximander, Heraclitus. Now despite the fact that Cos was spared any direct domination or long continued pressure, and was more free from the intimate mingling with Oriental forces brought by Persia to Miletus and even to Herodotus at Halicarnassus, we cannot doubt that where Hippocrates saw the light first, in an epoch when Persian political domination prevailed through the islands, medicine as Hippocrates revealed it to the world derived a not unimportant leaven of learning through Persian channels. The Cnidian sentences, of a supposed origin in Cnidus where Persian rule was harsh, we recognize as more Oriental than other parts of the Hippocratic books, but traces of the lore of Egypt and Babylon are unmistakable elsewhere also.

We get many a hint, often more than a hint—a conviction—from the pages of Herodotus, that Oriental influences profoundly affected, indeed originated, much of Greek thought. We get, in one of his anecdotes, a most dramatic one, a direct indication that Cos was no stranger to Persian tyranny at least. It is the incident of the woman who was a suppliant to Pausanias after his victory at Platæa in 479 B. C., which drove the remnant of Xerxes's mighty expedition out of European Greece.

"When the barbarians were annihilated by the Hellenes at Platæa," says Herodotus (4), "there came then to them a woman fugitive. When she heard the Persian power was destroyed and the Greek triumphant, being a concubine of Pharnadates, a son of Theaspes, a Persian man, she decked herself out with many gold ornaments—both herself and her waiting women and all her following in fine raiment. Alighting from her chariot among the Lacedæmonians, still busy with slaughter, she saw Pausanias directing everything and having been told his name and often having heard of his lineage she accosted Pausanias and clasping his knees she cried: 'O, King of Sparta, save me, a suppliant, from captivity, from the slavery forced on me by the spear, for thou hast prevailed here, thou hast destroyed those who have no reverence for the spirits of the dead nor for the gods. I am of a family in Cos, the daughter of Hegetorides, the son of Antagoras. The Persian has had me, seizing me by violence in Cos.' And thus she was answered: 'Woman, be of good courage, if you are a suppliant and if it turns out you are a daughter of Hegetorides, the Coan, for it happens that he was the greatest friend to me of all those dwelling in those regions.' Speaking thus he turned her over to those of the ephors present and later sent her off to Ægina, where she wished to go." This is a flash from a page of Herodotus but it lights up the text of Hippocrates where the close reader, familiar with the Zend Avesta and the Rig Veda, can not fail to trace the Oriental influences which came through them to the western world when Persians were hunting concubines in Cos.

In this story, besides its mention of Cos we get a glimpse of social conditions in the ancient Oriental empires, which have persisted more or less in the same form to our day. In the war we are waging in medicine on venereal disease we still get nowhere without a careful consideration and a firm facing of the social question where it involves the underlying sexual instincts of men and women by virtue of which the human race persists on this earth. The problem is that they arise to view most obtrusively as unruly passions which threaten social life and all political organization, the sheet anchors of our civilization. It is not a question alone of the cure and prevention of gonorrhea and syphilis. Somehow or other in destroying these we have got to preserve or evolve methods by which sexual desire is both gratified and restrained in a social culture which makes an ever increasing encroachment on the age of the puberty of men and women to prepare them for an ever increasing complexity with which they must struggle for survival and yet exert themselves most efficiently for the good of their race in after life. It is difficult so to compress the ramifications of this vexing problem in the compass of a single sentence as to make it stick in the memory as a coherent conception. Without some unification of an appreciation of the evils of venereal disease with an appreciation of venereal desire as the salvation of man, not as a social animal alone, but as any kind of an animal at all, we are sure to meet with disappointment, even despair, in our efforts to prevent syphilis and gonorrhea.

We do not know how much they suffered from gonorrhea in the old civilizations, not much probably. We do not know that they suffered at all from syphilis, but we do know that family life and the relation of the sexes were on a basis varying in detail very much indeed from our own, yet as we shall see very much like it in some of its forms and rituals. We have applied religion to the question and, of late centuries, a puritanical régime. They both mean sexual continence for the few, how few we do not know, and promiscuity for the many, how many we do not know, but the result has been that while society was thus evolving in western lands, venereal disease has sapped the virility of the race, until we are face to face with the problem in an ever worse form, and the sexual problem in an ever worse form—doubly worse now that we are entering on an era of the social emancipation of women. Must we find vaccines that will render the whole human race immune to syphilis or gonorrhea? That is a purely medical vision. Or must we regulate the relation of the sexes on some better, more liberal basis than has thus far been our ideal, more efficient to preserve the structure of social cooperation, so that progress may be made still further in alleviating the sojourn of men on this earth? That is not a merely social problem. It involves the physiology and psychology of sex. But could there be found any two propositions more chimerical than to answer these questions of despair with an unequivocal affirmative?

Whatever questions we put to ourselves, or whatever answers we make to them, could there be any more foolish way of questioning or a more imbecile way of answering than calmly to disregard the experience of other civilizations so far as it has been possible to present the facts in regard to them? Do we intend to resign ourselves to the ribald recklessness of the jest that syphilization and civilization go hand in hand? When we inquire into the venereal diseases of Babylon and the Nile, even of Rome and Greece, we are met with a shattering of that smart saying, so far as we have been able to ascertain. Certainly gonorrhea was not so rife, if common at all. If syphilis existed, it was in the chrysalis stage, both of them quite incomparably rare when we consider our own plight. I shall not repeat the various references (11) to records which indicate that gonorrhea certainly and syphilis possibly were known of old, but here in passing it may be permissible to refer to the case of Otanes (6), who led the conspiracy which put the great Darius on the Persian throne. This has not been so often adduced. When he was sent to subdue the island of Samos he made a dragnet extirpation of the inhabitants, men, women, and children. What other excesses he committed Herodotus does not tell us, but, "General Otanes helped largely in colonizing it again because of a vision seen in a dream and because of a disease which had seized upon his genitals." Probably it was the same which so plagued the Scythians when they sacked the temple of the goddess at Ascalon, to which Hippocrates also refers (12).

Before Plato dealt with the sexual problem in his Republic we get evidence in the pages of Herodotus that it confronted the civilization of Babylon—long before. The "whore of Babylon" has been held accursed from the time of Calvin to that of DeWitt Tallmadge, but she stands in history as an emblem of that striving after the solution of the problems which confront us today with the added complication of venereal disease, which could hardly have afflicted ancient society as it does us, if at all, so completely has it escaped the records of the past. The Persian practically and openly granted that liberty to man in the higher ranks which man has ever in our own civilization taken secretly to himself. Liberty was the license which consisted for one thing in unrestrained indulgence in sexual intercourse, early and multiple marriages, and numerous concubines. We are told the modern Oriental finds a female bed mate for his son as he rises into adolescence, perhaps in some negro slave woman. This solution of the problem we find traces of as invading Europe, from Asia and Africa perhaps, but it was never confined there.

In an especially stupid play, *The Asinaria,* which Plautus avowed he had from the Greek Demophilus, we get a particularly revolting mark of it, intended to be funny. We note with less repugnance but with some aversion the indulgent view of Goethe's mother as to his bed mate, the pitiable Christiane, whom he even finally married, an action due to that pressure of social justice which was beginning to make itself felt even at the courts of German princelings in the dawn of the nineteenth century. We hear occasionally even now, or perhaps it is better to say one or two generations ago, of mothers on both sides of the Rhine arranging for the mistresses of their sons. In the emancipation of woman, upon the era of which we are fully launched, is this to be endured or swept away? It is sure to become much more frequent, or else to be cast out as anathema. The abortive, noxious if you will, sprouts of this code of morality, or immorality if you insist, have sprung up at the very foundation stones of even our civilization. Stripping ourselves of our prudery or intolerance, if we must, we still fail to see how such arrangements are to fit in with the justice for the woman which her fellow women will surely insist on. It is evident that with the triumph of democracy and the triumph of woman and of many other things which war, "the father of all things," has brought to our doors, that we are on the eve of a radical change in the matter of sexual relations in our social fabric, but just what it is going to be, nobody but a prophet or his ass will venture to say. Surely neither the aristocrats with their concubines, nor the rich with their divorce courts, are longer going to enjoy a freedom from trammels laid upon our social system which bind only the poor and the virtuous and oppress with a stigma and suffering only the female. After all, licentiousness is a thing which grows with indulgence. Individual selfcontrol must in the end save us from mere promiscuity. But at what stage before that? That is the question. To suppose in the present state of political enlightenment that fornication and intoxication are to be the privilege only of the rich is a silliness that is astounding. A great exponent of democracy made the declaration to another generation at the approach of a great crisis that the state could not continue to exist, half free and half slave, and the supposition of only half revelling in wine and women approaches the ridiculous.

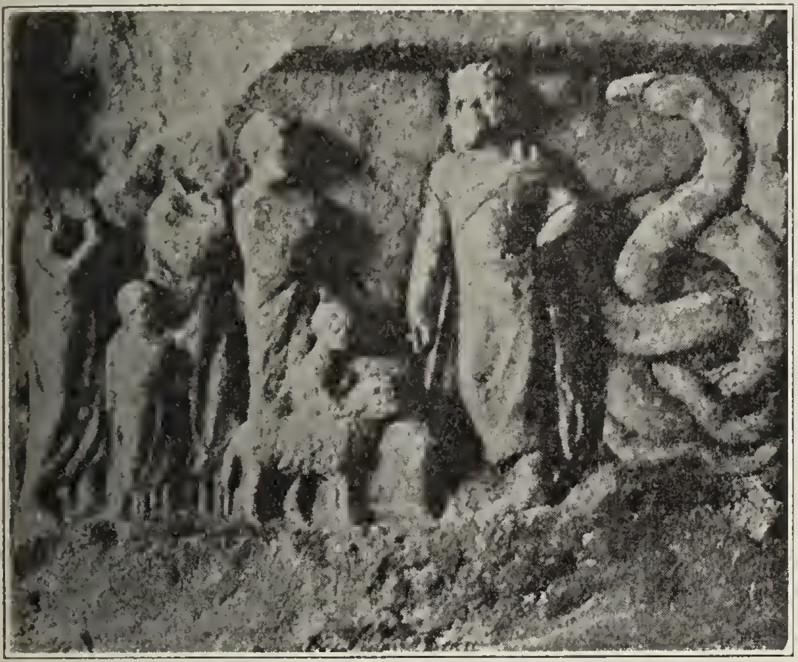

Fig. 2.—The snakes of Athens before Hippocrates.

These then are the considerations that cluster around the medical man's problem of eradicating sexual disease. This struggle with the problem of venereal disease by modern medical science, like every other struggle toward the light, needs the aid of historical perspective and as we look back along the track we have travelled since the time of Herodotus we find the path bristling with difficulties, and much the same difficulties, which are confronting us. At every crisis in social and political history we find sexual passions breaking over crumbling barriers into the light of day.

All these are fairly familiar to us in history, as is the system of concubinage which has prevailed more or less openly at all times in the past history of our own civilization in some form or other, but as to the "whore of Babylon" there are some peculiarities in the tale Herodotus tells of the hierodules of Babylon. There are other instances of sexual intercourse as a part of religious rites, but I am not familiar with any other we know about in a civilization which had reached such a height. What I wish to draw attention to is the part that it played in religion, all powerful in a state which was face to face with the regulation of sexual relations and whose legal codes were so strict, which was so resolute in keeping social order and in dealing out social justice, in a state the political evolution of which was so complex. It was in reality a license of prostitution by a theocracy determined to hold together an oriental political organization and it was doing it by an attempt to satisfy the natural instincts of man. Modern governments in large cities have attempted it without the aid, indeed with the open hostility, of religion.

Aside from the open concubinage on the part of the rich, which differs from our own largely in being open, in essentials the access of the male to the female under the sanction of law and custom was not radically different from our own, except, as with the concubinage, in being more open in the practice of its principles. Herodotus alludes (5) to the slave markets, but closely resembling these were the auctions of marriageable girls in the villages of the people themselves. He says it prevailed in Babylonia and among the Veneti (?) of Illyria. The highest bidder got the handsomest wench. With this we are familiar enough in its less frank form among us.

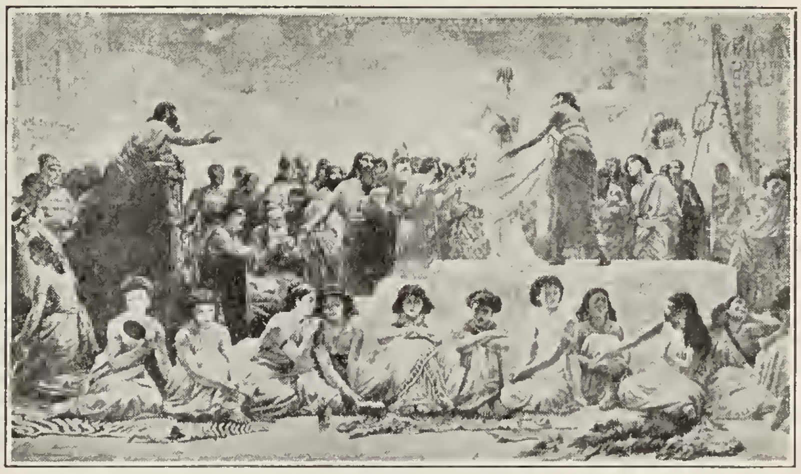

Fig. 3.—The Babylonian marriage market.

The charms of some of the girls brought a very low price. The money acquired from the sale of beauty was used to influence the acceptance of those without such charms. The dower of the bride in many countries of Europe is subventioned by private charity and in some it has been proposed to make it a state institution. Something of the kind probably could be done to establish early marriages and it might be a step in the rational campaign against venereal disease. It certainly is preferable to "birth control." The account of Herodotus runs: "A father was not allowed to give his daughter in marriage to whom he pleased, neither might a purchaser carry off a maiden without security, but he was first obliged to give security that he would certainly marry her. A law was enacted that if they did not agree the money should be repaid." We see this was, in form at least, a very much more insistent intrusion on the part of the state than our own could at present undertake, but it did not differ in principle. The bridegroom bought his bride not from her family but from the state and the state could presumably reimburse in part the family, but what is more to our purpose it could thereby supervise eugenic matings, promote early marriage and make its covenants more widespread among the plain as well as the fair young women. Today such an arrangement could still more efficiently supervise the detection and root out the existence of venereal disease. I am sure that this would appeal to some vexed and despairing social workers as an unattainable but a devoutly to be wished for consummation of a praiseworthy ideal.

But there is a fly in the amber. It is the hierodule, which I am afraid we must accept as a hint that all was not well with the sexual problem in Babylon. Every marriageable woman, high or low, rich or poor, must sit in the temple once in her life, until some male saunterer in its cool precincts should drop a coin in her lap and she must submit to his embraces. This evidently was the "whore of Babylon," which served as a missile for disputatious theologians to hurl at one another long ago, but for us she is the symbol of a further attempt on the part of an hierarchical state to facilitate and regulate and supervise the congress of the sexes. It was a holy sacrament outside of our holy sacrament of marriage and repugnant in the last degree to our ideas. Moreover, we can not fail to see that then as now the barter and sale of brides, even when in the hands of the state instead of in those of the family, was insufficient to regulate the relation of the sexes. The institution of hierodules was an appendix in Babylon to the barter and sale of brides, but the latter does not appear to us, for certain reasons (can it be because we are used to it?) half so horrid as the former. In fact the whole question is revolting to our moral sense, but I fear that our moral sense is subject to distortion and if we are going to deal efficiently with venereal disease it behooves us to get some of the twists out of it, for venereal disease is a worse horror than anything else that ever befell mankind.

The Results Obtained by Various Methods in the Treatment of Tumors of the Bladder*

By HUGH H. YOUNG, M.D.,

and

W. W. SCOTT, M.D.,

Baltimore, Md.

The surgery of vesical tumors has been the subject of much discussion and during the past ten years many new procedures have been advocated. In 1915 Gardner analyzed 666 cases of bladder tumor, in which operation was performed by various surgeons, and found that in 224 cases of resection recurrence developed in 43.7 per cent., in 442 cases of excision of the growth only, recurrence occurred in 88 per cent. When we realize that many of the tumors are benign we see how unsatisfactory the methods are.

In a careful statistical study of 202 cases of vesical neoplasms, operated in during a period of ten years ending in 1919, Judd and Sistrunk (1) have given us a fair presentation of what may be generally expected from modern surgical methods. The hospital mortality was 12.9 per cent. and within two years after the operation 58.4 per cent. of the patients were dead. Of the sixty-four patients who were alive only fourteen had gone more than five years since operation, so that good results lasting for a period of five years were obtained in less than seven per cent. of the cases. The methods employed and the immediate hospital mortality were as follows:

---

*From the Brady Urological Institute, Johns Hopkins Hospital. Read before the New York Academy of Medicine, November 16, 1922 (by invitation).

Resection of tumor, with an area of entire bladder wall, 102 cases, deaths in hospital 15.9 per cent.
Excision of tumor and adjacent tissues, sixty-six cases, deaths in hospital nine per cent.
Transplantations of ureter in connection with resection, thirty-six cases, deaths in hospital twenty-two per cent.

Cases treated by fulguration and by radium are not included, so that Judd and Sistrunk's report may be taken as an example of what may be expected by radical surgery at its best.

Barringer (2), in 1921, presents the results obtained by him in the use of radium. Summarizing his cases we find that in twenty-nine cases of carcinomatous tumor of the bladder treated by radium introduced through a suprapubic wound, seven patients were examined subsequently cystoscopically and found to be well, and one wrote that he was well—total patients well, twenty-seven per cent. But a very short period, varying from two to twenty months, had elapsed since operation. Eleven cases, all but one of which were diagnosed microscopically by Dr. Ewing to be carcinoma, and seven of which were large, extensive or multiple, were cured by the use of radium introduced cystoscopically. Three of these had been followed for four years (twenty-seven per cent.) and only three less than one year, so that a hopeful picture is presented of the results with radium.

In a more recent paper Barringer (3) reports cases and more detailed analysis of the results obtained in cancer of the bladder. The reports show most remarkable results. In nine operative cases, which were treated by intravesical implantations of radium, all the patients but one were cured. In twenty-one cases of inoperable carcinoma of the bladder, which were treated by implantations of radium through suprapubic wound, the tumor was removed from the bladder in all cases but in three recurred. One patient died from radium slough of the bladder, and in one of these three the recurrence was beyond the bladder. These statistics are certainly the best that have yet been obtained in extensive and socalled inoperable cancer of the bladder.

It is thus seen that there is much question as to what is the best method of treating tumors of the bladder and as I have been asked to present a paper on the results obtained by various methods in tumors of the bladder, I have seized the opportunity to collect all our cases at the Brady Institute and to study as thoroughly as possible the ultimate results. (Some of the cases are my own, but the majority were treated by my associates Dr. Geraghty, Dr. Frontz, and Dr. Colston, to whom I am very grateful for the privilege to use their private cases, and for much enlightening assistance and advice. *H. H. Y.*)

I. SUPRAPUBIC CYSTOSTOMY.

This has been used in extensive and supposedly inoperable cases; was very frequently employed at one time and now is rarely used except in conjunction with radium which will be considered later. I shall not take time to analyze the results of suprapubic drainage, which is manifestly only a palliative procedure.

II. EXCISION OF THE TUMOR WITH AREA OF HEALTHY MUCOUS MEMBRANE OR PEDICLE.

I find twenty-eight cases in this class, in nearly all of which the tumor was clamped across the pedicle, traction made, elongating the pedicle and drawing up the adjacent vesical mucosa which was then excised with a cautery well away from the tumor. In most cases this seemed a quite radical removal of the papillary tumor, but poor results were obtained. Recurrences occurred in all but three of these twenty-eight cases, and the time elapsed since operation was under one year in two of the cases (both papillary carcinoma) and one five years. Three patients have not replied to letters; three have died, cause unknown; sixteen have died of recurrence (eleven within two years of operation).

To summarize: In only eleven per cent. of these cases may a cure be possible, and the present ultimate mortality is already sixty-eight per cent. Among these were three cases, apparently benign papilloma, removed with great care with a healthy area of mucous membrane, all of which recurred "malignant" and the patients died after subsequent operations. The twenty-eight cases in this group, all of which were thought to be favorable for complete removal by the operation performed, furnish a positive demonstration of the futility of this technic, and bespeak either more radical resection of the bladder or the use of radium or fulguration.

III. DESTRUCTION OF TUMOR AND INFILTRATED AREA OF BLADDER WALL WITH CAUTERY.

There are fourteen cases belonging to this category. All were malignant, usually with extensive infiltration of the bladder wall, and most of them were too extensive or too apparently hopeless to consider resection. Of these fourteen patients, nine have died of cancer. Two are alive, apparently doing well after operation four and eight months ago—too recent to speak of as ultimate results. There remain three cases in which remarkable results have been obtained, as follows:

CASE I.—No. 7138. The patient, aged forty-eight, with a large infiltrating carcinoma on the right side of trigone, involving the prostatic orifice, was operated upon in September, 1918. A suprapubic cystotomy was performed, with removal of papillomatous portion with cautery, deep cauterization of base and adjacent bladder wall and prostate. Recurrence took place one year later; operation was repeated, and the tumor cauterized thoroughly. Cystoscopy was performed on August 13, 1920, bladder was clean, and there was no evidence of cancer (duration two years).

CASE II.—No. 7502, papillary carcinoma three by four cm. in diameter on left lateral wall; suprapubic destruction of tumor with deep cauterization of base and adjacent bladder wall. Examination ten months later showed no recurrence.

CASE III.—J. F., aged fifty; infiltrating papillary carcinoma; suprapubic cauterization of tumor and base. Small recurrence destroyed by fulguration. Examined September, 1920, no recurrence (nine years since cautery operation).

These cases show that exceptionally good results may be obtained by deep destruction of infiltrating tumors with the red hot cautery, either Paquelin or electric. The same effects may be obtained by the cold cautery if deep penetration and destruction of adjacent bladder wall and vesical orifice and prostate (if involved) is obtained. In fact, far more can thus be accomplished than by resection in tumors involving the vesical neck and prostate. One patient died of streptococcus infection following suprapubic cauterization of a bladder cancer—the only operative death: operative mortality seven per cent. Two cases should be cited here.

CASE IV.—No. 2216. The patient, aged thirty-five years, had perhaps a hundred papillomata, mostly minute, scattered all over the bladder but several of moderate size. The bladder was opened with care not to infect prevesical tissues, the tumors completely destroyed with the electrocautery, the bladder treated with twenty per cent. resorcin and closed. Several years later small recurrences occurred, but were cured by fulguration, and on two examinations ten and thirteen years later the bladder was found well on cystoscopy.

CASE V.—No. 2286. The patient had enlarged prostate and vesical tumor, had been treated elsewhere by repeated x ray therapy through the perineum. The cystoscope showed a large round necrotic tumor on the right side of the trigone, and at suprapubic operation it was found to be about two inches in diameter and so necrotic that it was scooped out with ease, having a rough base which was deeply cauterized with the Paquelin. Perineal prostatectomy was also done. Two years later the patient reported himself quite well. The microscopic diagnosis was malignant papilloma.

This apparently remarkable result of the x ray in causing almost complete necrosis of a large papilloma is unique. Both of these cases show the value of cautery destruction of tumor bases. Compared with mere excision of the tumor and pedicle with cautery, even in the apparently favorable and supposedly benign cases in which that was used, as shown in section I, deep cauterization is shown to be of far greater value, and is particularly valuable in infiltrating tumors, especially around the vesical orifice and trigone. It remains to be seen whether radium applications or suprapubic implantation of emanations can give better results. Much more detailed study of such cases, over a period of years, is required, and detailed statistics on these questions should be given by the great clinics.

IV. RESECTION OF BLADDER WITH TUMOR.

There are fifty-one cases in this group in which a radical attempt was made to remove not only the tumor but also a wide area of surrounding bladder wall. These cases have been analyzed as follows: Ages thirty to thirty-nine, two; forty to forty-nine, seven; fifty to fifty-nine, sixteen; sixty to sixty-nine, twenty; seventy to seventy-nine, five; not given, one; total, fifty-one.

Previous operation: Suprapubic excision, four; removal with cystoscopic rongeur, one; radium applied with Young's cystoscopic applicator, two; massive radium treatment through abdomen, one; deep x ray therapy, one. The tumor was single in forty-eight cases and multiple in three cases. In six cases the area of resection included the lower end of one ureter. The results have been tabulated according to pathological diagnosis. (Table 1.)

The recent introduction of radium has been followed by so many surprising, and occasionally amazing results, that we cannot now say definitely how much radical resection of vesical tumors of malignant type—particularly the infiltrating type—should be given up for radium or deep cauterization or both combined. Several years more of experience with radium and careful study of cases will be required before we shall be prepared to give up wholly resecting as radically as possible in apparently favorable cases of carcinoma. An interesting case was one of carcinoma of the posterior wall of the bladder in which, on opening the abdomen, we found the cecum adherent to the bladder. Investigation finally revealed a carcinoma of the appendix which involved the bladder, a wide anastomosis (?) of which was made along with a resection of the lower portion of the ascending colon and cecum, and a part of the ileum. Anastomosis of ileum to colon was carried out by Dr. Mont Reid while we repaired the vesical defect. The patient has had an excellent result—cystoscopy showing no recurrence after two and a half years.

Pt. dead—recurrence (cancer)....	1											
Pt. dead—"other cause".........	3											
Pt. dead—cause unknown........	2											

Four patients with infiltrating carcinoma showed no improvement under fulguration; two are known to be dead of cancer, and two have been lost sight of. Likewise, three patients with papillary carcinoma showed little improvement from fulguration and all these are now dead. In two cases, diagnosed malignant papilloma, the tumors were destroyed by fulguration and in one the patient is well now five years later. The other patient has been lost sight of.

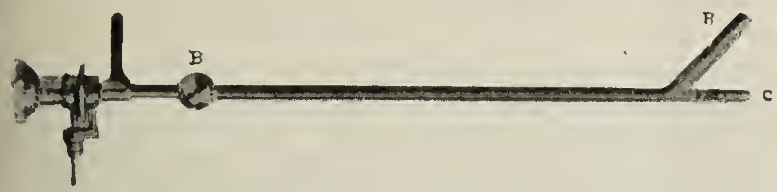

Fig. 1.—Young's cystoscopic radium applicator with ball; b, externally for attaching fixation clamp; c, cystoscope; r, radium in platinum tube.

Summarizing the whole group of thirty-seven cases we see that fulguration has been valuable only in papilloma, both benign and malignant. For papillary and infiltrating carcinoma it has been worse than useless, as some of these patients might have been cured by timely resection, by deep cauterization, by radium, or by a combination of these procedures.

The results shown above in benign papillomata demonstrate the great value of fulguration in this class of tumors. The results are much better than those obtained by suprapubic excision with cautery, and when recurrences have occurred they were readily treated by additional fulguration, whereas after suprapubic excisions the recurrences have been more extensive and sometimes prevesical and very malignant.

Among the twenty-seven cases of benign papilloma the hospital records show that in all cases the tumors were completely destroyed by fulguration so that the immediate results were good. In fifteen cases the patients are reported well, as tabulated above, and three cases not heard from recently were well over two years. Three patients in whom the tumors had been completely destroyed died, respectively, of pneumonia, prostatectomy and accident. We have, therefore, twenty cases apparently cured, or seventy-four per cent. Some of these patients have not been cystoscoped recently so that this figure is probably too high.

VI. 103 CASES TREATED BY RADIUM AND FULGURATION THROUGH CYSTOSCOPE.

In 1914, following Pasteau's publication of three cases of cancer of the prostate and bladder treated by radium introduced through a catheter, one of us devised an operating cystoscope for the accurate treatment of bladder tumors with radium, and in May, 1915, presented to the American Urological Association three instruments for placing radium in different portions of the bladder, each to be used with a cystoscopic clamp, by means of which the instrument was held fast to the table and the radium thus kept at the desired place on the tumor (Figs. 1, 2, and 3). The originality consisted not only in applicators operating around a straight cystoscope by means of which the radium could be accurately placed, but particularly the use of the fixation apparatus. During the past nine years these instruments have been in almost daily use and we are now in a position to determine their clinical value; firstly, by a study of 103 cases in which radium, thus introduced, has formed the main attack upon bladder tumors. All of these cases have also had one or more fulgurations, as it was soon discovered that the combination worked better in almost all cases than either alone. It has been proved that large papillomata, particularly of the malignant type, respond much more rapidly after application of radium when subsequently fulgurated, as previously reported by Dr. J. T. Geraghty.

The technic employed has been to apply a tube of one hundred mg. of radium, by means of the appropriate instrument, every day or two, to a different portion of the tumor, for a period of one hour, during which time it was held in place by the fixation clamp fastened to the table (Figs. 4 and 5). After several radium treatments, fulguration was given intermittently with the radium, in large tumors each being used eight or ten times, and the radium occasionally afterwards (as much as 1,700 milligram hours). The analysis of these cases is as follows:

TABLE III.

RÉSUMÉ OF 103 CASES.

25 diagnosed benign papilloma, 78 malignant.
Good result, 60 per cent; poor result, 34 per cent; doubtful, 5 per cent.
Among 58 malignant cases, 46 were fairly hopeful cases.
Result: 36 successes, 75 per cent.; 10 large infiltrating carcinomas, all failures; 7 extensive papillary cancer, all failures; benign papillomata 25, cured 23, followed 1 to 7 years.

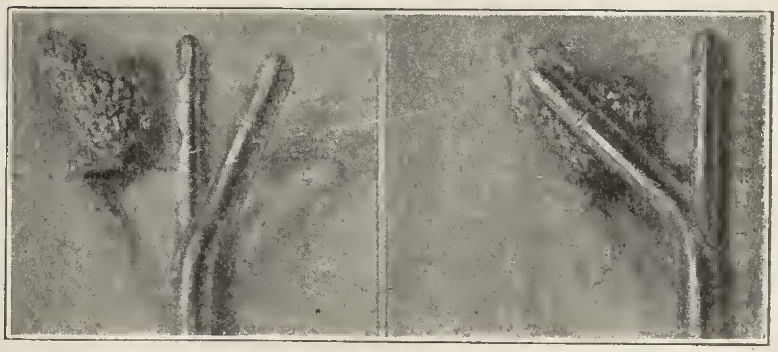

Fig. 2.—Showing the steps in the application of radium to a malignant papilloma in the region of the right ureteral orifice.

As seen in the tabulation given above the benign papillomata, although many were multiple and several very large, have almost invariably been destroyed and ultimately cured. Several of these tumors in which fulguration had been tried without effect, disappeared very quickly when radium was applied several times (500 to 800 MH) followed by fulguration—which is undoubtedly a valuable adjunct to the radium. The results in some of these cases is indeed brilliant. The effects of the treatment is far less constant in the malignant cases as shown by the following tabulated study of cases in which satisfactory notes are present:

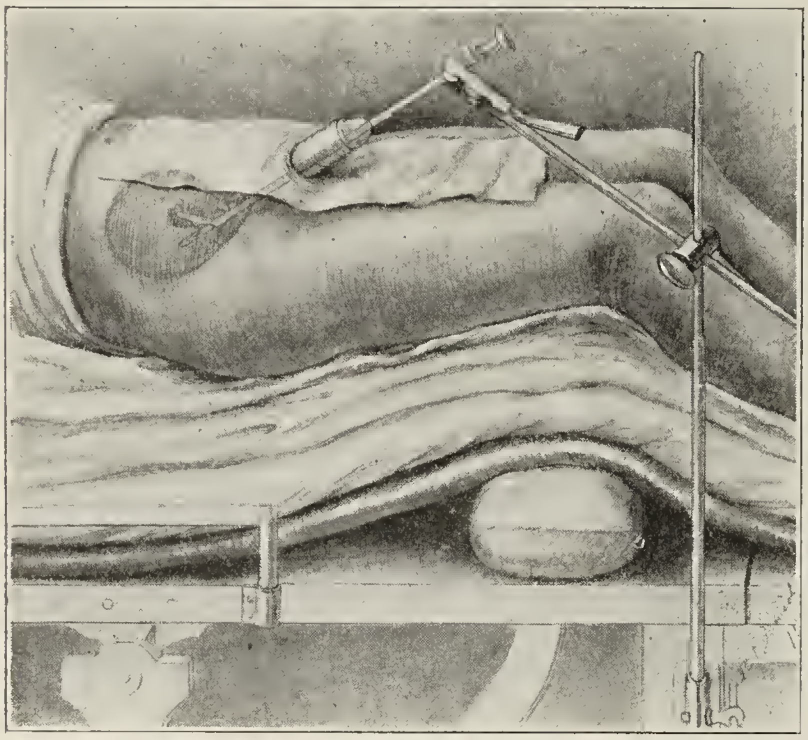

Fig. 3.—Showing use of cystoscopic radium applicator with fixation clamp fastened to table. (Transparency indicating the use of the instrument in the bladder against a vesical tumor.)

TABLE IV.

Radium and fulguration in malignant vesical tumors

No.	Pathological diagnosis			Immediate results		Final results	
				tumor destroyed	tumor not destroyed	tumor recurred	well
33,	Malignant papilloma.	small	11	11	0	1	7
		large	15	14	1	3	8
		multiple	7	7	0	1	3
20,	Papillary carcinoma.	small	4	4			4
		large	11	7	4	6	2
		multiple	5	2	3	2	1
13,	Infiltrating carc.....	small	1	1			1
		large	10		10	8	
		multiple	2		2	2	
1,	Adenocarc	small	1		1	1	

This table would be more satisfactory if the ultimate result were more accurately known in all cases. Where there was doubt as to condition of the patient or the cause of death, they were placed under the query column. The statistics, however, are sufficiently definite to show that, whereas the results obtained are not so good as in benign papillomata, they are really surprisingly good in malignant papillomata and small papillary carcinomata. In large and multiple cases only three patients are recorded as well out of sixteen of these cases. In the infiltrating carcinomata only one case (and that small) is reported cured out of thirteen cases.

In summing up, it may be fairly said that vigorous treatment with radium (100 mg.) applied accurately by a Young cystoscopic applicator and fixed *in situ* by a clamp, followed by fulguration, gives results far superior to fulguration alone in benign papillomata, particularly of the large type, which are often completely resistant to fulguration alone; that in the majority of papillary carcinomata, some large and multiple tumors, radical results may be expected in two thirds of the cases; but that in the infiltrating carcinomata, unless small, this form of treatment is useless, and time should not be wasted in attempting it.

A study of the cases shows that the successful cases have received from 500 to 100 MH. of treatment (five to ten hours with a 100 mg. capsule of radium) and a few cases greater amounts. Among the unsuccessful cases most of the patients received less than 500 MH. but others received very full treatment without success. In cases where the vesical neck or prostate was involved the posterior urethra was treated with the simple (noncystoscopic) applicator, generally supplied with two 100 mg. tubes of radium placed tandem (Fig. 6). In cases where the base of the bladder or trigone or prostate was involved rectal applications were also made. In one such case the treatments were recorded on charts, as shown in Fig. 7. The results of such multiple avenues of attack was in some cases really extraordinary—not only in removing induration and infiltration but also obstruction to urination as well as hemorrhage. By careful placement of the radium on new sites each time, overlapping is prevented and rectal, urethral and vesical burns are quite avoidable. The use of instruments in rectum, urethra and bladder, without accurate determination of the location and fixation at that location, cannot be too strongly condemned. The crux of successful radium treatment is accuracy, and without an accurate technic the use of radium is reprehensible.

In one case, a woman aged seventy-eight years, a very large globular papillary carcinoma was found occupying the whole of the trigone and reaching the vesical orifice. In February, 1917, we implanted needles containing 120 mc. of emanations into the tumor through our tubular urethroscope. The shaft of the needle came out through the urethra.

We were amazed at the rapidity with which this very large tumor disappeared with very few treatments of radium alone. Two years later the patient returned with a tiny, matchhead sized recurrence, which was destroyed by fulguration. She has since been cystoscoped and found well and now, October, 1922, writes that she is well (five and a half years later). More recently Neill (?) has devised an excellent instrument for introducing small emanation tubes into vesical tumors and has reported excellent results. Barringer has employed the catheterizing cystoscope for the same purpose, and very recently Buerger and Cunningham have added technical modifications. It seems probable that endovesical or cystoscopic implantation has a bright future in the treatment of certain bladder tumors.

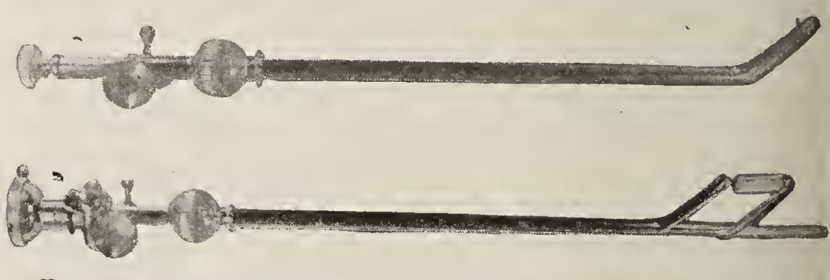

Fig. 4.—Instrument No. 2 closed and open. This carrier is of value for radiating cancer of the seminal vesicle through the bladder when the carcinomatous invasion extends far lateralward.

VII. FIFTEEN CASES OF CARCINOMA OF THE BLADDER TREATED BY IMPLANTATION OF RADIUM THROUGH SUPRAPUBIC CYSTOSTOMY.

In most of these cases an extensive carcinoma was present and they would ordinarily have been adjudged hopeless. As is often the case with radium, it was used in a forlorn hope of arresting the dread disease. Nine of these patients are known to be dead. No reply has been received from three, in two of which improvement was noted as a result of the treatment.

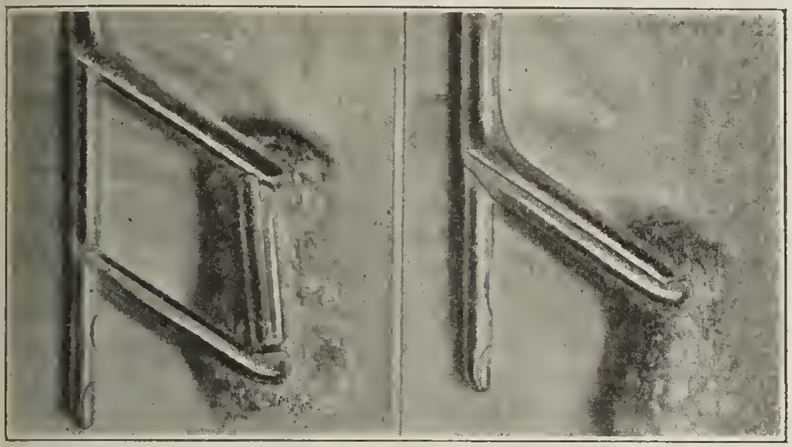

Fig. 5.—The instrument shows the steps in the application of the radium to a tumor back of the ureteral orifice.

Case VI.—One patient, A. H. L., No. 10447, aged seventy, with an infiltrating carcinoma involving the right side of trigone and right posterolateral wall of bladder, received twelve emanation points containing a total of thirty mc. of radium. The immediate result was excellent, the tumor disappeared completely and on discharge the cystoscopic examination showed no tumor present, but the patient died one month later of cancer.

Case VII.—Another case, H. B., No. 8761, aged sixty-five, presented a malignant papilloma, which involved the right half of the trigone, ureter and adjacent lateral wall of the bladder. Treatment by fulguration and radium, 400 MH., by cystoscope was first tried, and then subsequently suprapubic cystostomy was performed and the tumor excised and base cauterized and two "points," four mc. each, were implanted. Reccurrences took place which were treated by fulguration successfully and the patient reports by letter, now two and one half years later, that he is well.

Case VIII.—No. 9450, G. A. R., aged fifty-two years. Large infiltrating carcinoma of left lateral wall involving vesical orifice and trigone to midline; size two by two and a half inches. Deeply cauterized and implantation of four emanation tubes three and a half mc., each imbedded in central portion. These were removed in twelve hours. One year later the patient was apparently well.

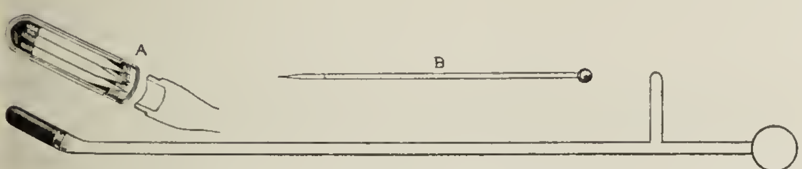

Fig. 6.—New radium applicator with enlarged cap, a, made to contain four needles containing 12½ mg. of radium each, which may be used also for needling through the perineum by means of attachable shaft, b.

Case IX.—No. 9722, A. C., aged seventy-two. Large infiltrating papillary carcinoma of right lateral wall, trigone and vesical orifice, size two by two and a half inches. Deeply burned with cautery by Dr. Geraghty; ten emanation tubes 1.6 mc. each implanted around periphery and two radium needles twenty mg. each in centre. Eighteen months later reported well.

Case X.—In contrast to these four favorable results, another case, C. F., No. 8678, with four small tumors less than one cm. each in diameter and not infiltrating (but found microscopically to be adenocarcinoma) was treated by eight emanation tubes, two and three quarter mc. each, placed one cm. apart, with distressing results, Shortly after operation the patient began to suffer excruciating pain in the bladder, which persisted for months regardless of a subsequent suprapubic excision of a large area of necrotic tissue at site of implantations. Death finally resulted six months later from metastases (apparently—autopsy not permitted). The latter case showed the danger of inserting emanation points of more than one half to one mc.

The fact that our experience with radium emanation points, inserted suprapubically, is not more satisfactory cannot be offered as evidence against this form of treatment. Barringer has reported a few excellent results with it and we intend to give it further trial—using points of small dosage, in reasonably favorable cases of infiltrating carcinoma, which are not in locations favorable for radical resection. The comparative value of radium implantations, and deep cauterization, several successful usages of which have been reported elsewhere in this paper, must be determined by further study of cases and results. In the three apparently good results cited above deep destructive cauterization was employed before implanting the radium.

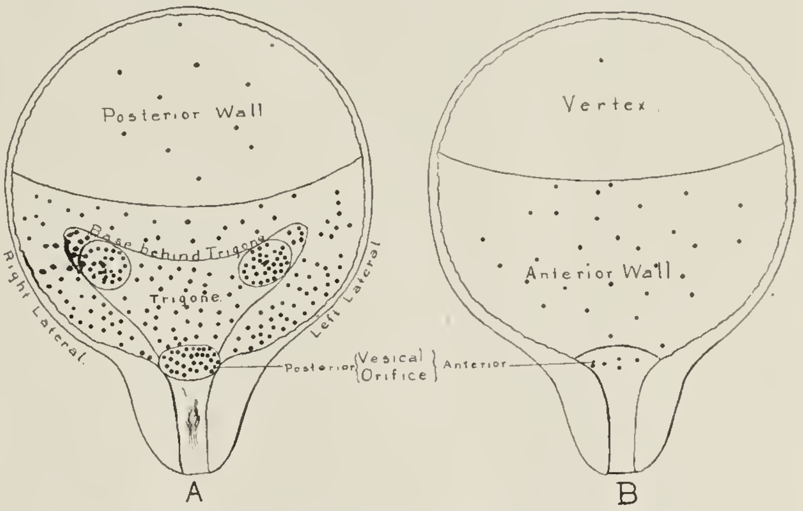

Fig. 7.—Diagram of the interior of the bladder on which has been plotted the location of the tumors in 209 cases of vesical neoplasm, benign and malignant. It is to be noted that only one tumor was found on the vertex, ten on the posterior wall, twenty on the anterior wall and the majority on the trigone and particularly around the ureters and at the vesical orifice.

CASES NOT TREATED.

There were fifty-four cases in which no treatment was given at our clinic for the tumors in the bladder, as the cases were considered inoperable. Twenty-eight of these patients are known to be dead, and many others have not been heard from and are probably dead. Many of these were operated upon a long time ago and at the present time would be treated differently. We would now not be satisfied with simple suprapubic drainage except in exceptionally extensive and manifestly hopeless cases, since the experience of Dr. Geraghty and ourselves with a few remarkable results from cauterization in extensive infiltrating carcinomata of the vesical neck and trigone and more recent cases treated by both cauterization and radium implantations—cases which seem absolutely beyond hope of even temporary improvement.

RELIEF OF DYSURIA—REMOVAL OF PROSTATIC OBSTRUCTION.

In six cases operations were carried out to remove prostatic obstruction, in the presence of supposedly inoperable bladder tumors. In two cases the Bottini electrocautery operation was performed with distinct benefit—urination became less difficult and frequent. In two more recent cases perineal prostatectomy was done with marked improvement in micturition during the five months the patient lived. In the other case the patient has been lost sight of. In another case in which the cystoscope showed a median bar obstruction a Young punch operation was carried out with benefit. In a sixth case, after destroying a pedunculated malignant papilloma with the cautery, a suprapubic prostatectomy was done, and at last report, four months later, the patient was apparently well.

The question of what to do for prostatic obstruction in certain cases of bladder tumor is an important one. Where the obstruction is due to infiltration or tumor growth at the vesical neck or adjacent portion of the prostate it may be relieved by vigorous suprapubic cauterization of the prostatic orifice along with destruction of vesical growths (with or without radium). Where it is evident that nothing is to be expected from suprapubic operation, radium, applied through the urethra, may give marked relief. We have frequently given 500 to 800 MH. per rectum, with good effect. Where the obstruction is due to definite hypertrophy nothing much can be expected from radium, and prostatectomy may be required. Barringer stated that he used the punch operation for certain obstructions due to malignant disease of the prostate, and we have had a few successes with it.

RÉSUMÉ:

A review of the 380 cases which have formed the basis of the report shows that:

About eighty per cent. of bladder tumors occur between forty and sixty-nine years of age, being about equally distributed in these three decades. A benign papilloma in a boy of fifteen years, and a carcinoma in a man twenty-six years of age were encountered, but as a whole the malignant tumors occur somewhat later than the benign.

Both papillomata and carcinomata are much more frequent in the region of the trigone and ureteral orifices and adjacent lateral walls of the bladder and vesical neck. The anterior wall is less frequently involved and the vertex and upper posterior wall are much more rarely involved.

The vertex, anterior, upper lateral and posterior walls are most suitable for resection and excellent results may be expected by radical removal of a wide margin of bladder wall, but that good results may be obtained by resection in the base of the bladder and region of ureters. When the vesical neck and prostate are involved deep cauterization is far more effective than excision.

Fulguration is the method of choice in benign papilloma, but in large tumors radium is of great assistance in causing a rapid disappearance of the tumor, and, owing to the potential malignancy of all vesical papillomata, radium should generally be applied, if possible. In malignant papillomata radium, applied with an operative cystoscope and held firmly in position with clamp fastened to table, is of first value and gives more brilliant results. Here again the conjoint use of fulguration and radium is advisable. The same treatment is sometimes completely effective in papillary carcinomata, and four small and two large tumors of this type and one small infiltrating cancer have been apparently cured by it.

Where the tumor is definitely malignant or very extensive, and particularly if infiltrating, it should be attacked suprapubically; great care being taken not to touch the tumor or break off any papillary processes, and alcohol or resorcin twenty per cent. applied to destroy any that may have dropped into the bladder or wound.

If resection can be carried out successfully with a wide area of healthy bladder wall, whether extraperitoneal or transperitoneal or with transplantation of a ureter, it should usually be done, but the operation should not be so extravagantly extensive as to face a very high mortality rate.

The position of radium implantation is still *sub-judice.* A few brilliant and remarkable cases are reported and we have had some, but always associated with deep and widespread cauterization. Viewed as a whole, however, the gloomy outlook which was held as to the curability of bladder tumors has passed. Fulguration, radium, the electrocautery and careful radical resection have transformed the situation, so that now about ninety-five per cent. of the benign and seventy-five per cent. of the malignant papillomata; about fifty per cent. papillary carcinomata and somewhere near twenty-five per cent. of the infiltrating carcinomata are probably curable by one or more of the methods above referred to.

There is no phase of surgery in which during the last ten years more gratifying advance has been made than in that of tumors of the bladder.

Treatment of Gonococcic Epididymitides With Intravenous Injections of Calcium.—Proceeding from the clinical experience that calcium shows good results in exudative inflammatory processes, Ernst Radnai (*Wiener klinische Wochenschrift,* November 16, 1922) injected five to ten c. c. of a ten per cent. calcium chloride solution intravenously in two cases of gonococcic epididymitis, with the result that the pains were diminished within a few hours and that the swelling of the cord and epididymis were reduced within twenty-four hours with a striking improvement in the general condition.

Retention Neurosis of the Bladder, Secondary to Postoperative Catheterization*

By VICTOR COX PEDERSEN, A.M., M.D., F.A.C.S.,
New York.

From the viewpoint of the urologist, there are often both peculiarity and futility in the commonplace order to catheterize about eight to twelve hours after operation. The peculiarity of the order lies in the fact that the excretion of the urine is necessarily decreased by the anteoperative starvation and catharsis, by the postoperative inhibition of the narcosis and depression of the surgical intervention (perhaps augmented by shock) and by sedative medication for pain and other undesirable primary sequelæ. In my opinion a better rule is that inculcated at the New York Hospital when I was an intern on the division of Dr. Robert F. Weir and the late Dr. William T. Bull. This rule was that no patients were to be catheterized within twenty-four hours after operation unless there were special reasons for earlier relief resident in the urinary system itself.

If the patient complained of a full bladder, the symptom was verified by physical examination—percussion or palpation. Then rather than an early resort to catheterization, a glycerine suppository or small low enema was employed in order to stimulate the bladder reflex through the rectal reflex. In this way the possibility and probability of vesical infections were avoided and, of almost equal importance, annoying hysterical impressions and retention neuroses were not excited, requiring several catheterizations each day for several days or weeks. In illustration of the wisdom of this policy, brief mention is worth while of four female patients. All had been operated upon the day before for pelvic or abdominal conditions. When about twenty-three hours had elapsed without the evacuation of the bladder by any one of them, and while the staff was again operating, the usual written report was received from the nurse, requesting special orders. Two glycerine suppositories were ordered for each woman, with a request for another report within an hour. In considerably less time than one hour another written report announced that all four women had evacuated their bladders naturally, under the stimulus of the suppositories.

In contrast with this simple experience is the following report of a case of retention neurosis secondary to postoperative catheterization, which is perhaps far more common than is usually realized.

Case I.—J. O., admitted to the urological service of St. Mark's Hospital, July 27, 1922. Case No. 3076, female, aged seventeen, Pole, single, no occupation. Her family history was negative, as was also her former personal history, with special reference to urinary disorders, such as enuresis and suppurative and catarrhal inflammation. About five months ago the patient was operated upon at one of the hospitals of this city for chronic appendicitis. An order for early catheterization was given, but in this case it led to a retention neurosis, or hysterical manifestation, which reached the unusual limit of the patient refusing to admit the feeling of a full bladder even when it could be seen and felt, almost as easily as a pregnant uterus at five or six months. At home this child had been catheterized three times a day by her mother for practically five months. Conversely, there were times in the ward when she insisted that her bladder was full when it was obviously empty on rectal and abdominal palpation or percussion.

As the patient did not give a history of disease of the nervous system in childhood and seemed to have no signs thereof on admission, I determined to see what could be done to create the opposite impression in her mind. The first order was therefore not to draw the water for forty-eight hours. This order was nullified by a hyperenthusiastic house officer who had her catheterized because she complained of pain in the bladder, whose fulness he did not verify by percussion. My order was repeated and reinforced by another that day or night I was to be notified before the catheter could be passed. A further direction was that as soon as she complained of a full bladder its condition was to be verified, and if distended it was to be emptied by giving the patient a high oxgall enema and that a large dose of cathartic was to be given so that within four, six or eight hours after the enema had made the bladder empty itself the cathartic would repeat the physiological process in a certain sense from a viewpoint more normal in the patient's impressions than the enema.

It is needless to say that both plans worked well and the child did pass urine, and did admit that she knew herself to pass urine. As she still insisted that she could not void by act of will we renewed the oxgall enema and catharsis treatment, after one day of rest therefrom. In the interval the nurse affirmed that the girl passed urine. The next step was to withdraw all aid whatever, such as the hot water bag, the enema, the cathartic, and small doses of morphine if a really full bladder agitated or distressed the patient, and then to inform the patient that she, herself, must relieve herself as best she could. It is noteworthy to state that she went nearly thirty-six hours without urinating, and did have a visible and palpable bladderful. But I stuck by my orders, and awaited results which were these. When she had to yield to the desire, she could no longer retain the urine, but flooded the bed and floor of the ward and hall on her way to the toilet, where she arrived with her bladder empty. One would think that the shame of such an experience would have conquered the neurosis. But the conquest was only partial. She was again allowed to fill up in the same way several times but was too cute and cunning to become the laughing stock of the other patients and the nurses in the same way. She now denied having emptied the bladder when the nurses knew that she did, and when physical examination proved that she had. I then tried the next moral step which was to inform the child that she could go home as soon as she could show reports by the nurses for three days in succession that she had voluntarily emptied her bladder at least three times a day. This test resulted in practically a consistent and satisfactory demonstration, and the child was discharged greatly improved after twenty-four days of worry and work over her in the hospital.

---

*Case report read before the Section in Urological Surgery of the New York Academy of Medicine, December 20, 1923.

A cystoscopy was done by my chief of clinic, Dr. Goldfader, before her admission to the hospital. During the irrigation and distention of the bladder the patient said she had no knowledge of the viscus. The examination showed a normal bladder with moderate trigonitis, apparently of traumatic origin. One would expect a vicious infection to supervene promptly upon home catheterization in an ordinary tenement house, but the child seemed to have escaped at least the severe varieties. A control cystoscopy and urethroscopy were done by myself as soon as the child began to respond to the nonintervention policy. The trigonum and urethra were both granular and unhealthy, although not in a state of actual infection and inflammation. The child had neither vulvitis, vaginitis nor urethritis. The nurses reported that after careful observation by them the girl did not masturbate.

That she had a reasonably normal cerebrospinal system was proved by a physical examination thoroughly carried out by my associate, Dr. Norman Sharpe, visiting neurologist. That she had a weak mentality was illustrated by the fact that she was in bed for only a few days next to a girl having hereditary cerebrospinal syphilis with epileptiform seizures, which she proceeded to imitate quite successfully when she complained of pain in her bladder, including even the twitchings of the face which were the aura of the fits of the other girl.

That her family had peculiar mental poise was illustrated by the fact that her mother raised a disturbance in the office of the hospital, during the period when we were allowing the girl's bladder to fill up. The mother was sure that the girl's bladder would burst. She even tried to climb the fire escape in order to reach the ward where her daughter was because she knew that the bladder had burst and that the girl was dying because we refused her admission to the ward on a nonvisiting day. What would or might happen to the child at home was indicated by the fact that the mother refused to believe reports by the nurse and by me of how successful her daughter had been in voluntary urination and agreed to believe only her daughter's admission if made within her hearing, and without the daughter's knowledge of her presence. With the mother hidden behind a screen the daughter acknowledged that she had passed her urine herself, but doubtless at home the weak policy of yielding to her whims will be resumed at no remote date. For such lasting result as such statements might have, the mother was told in very plain and vigorous terms that if she resumed catheterization the following would be the exact sequence of events for her daughter, in a short time rather than a long time—infection of the bladder, infection and destruction of the kidneys, and death.

In mentioning to my colleague, Dr. Frederick W. Smith, the chief details of the case, the suggestion was made that an x ray picture be taken for the remotely possible discovery of a spinal defect, such as partial spinal bifida. No x ray picture could be included in these notes because the patient and her family refused to have one taken. The laboratory reports showed a negative complement fixation test for syphilis and a urine which was acid, yellow, cloudy, specific gravity 1.012, marked albumin, no sugar, no blood, no casts, few pus and epithelial cells and many bacteria. No culture was done to determine the kind of bacteria present.

In literature cases much like mine are discussed under divergent diagnoses. Of these the following are examples: hysterical retention, retention due to posterior urethral lesions, retention due to nervous causes, or retention due to catheter fear and hysterical ischuria. Ischuria adds another lesion, namely, suppression. Ischuria paradoxa is excessive retention with constant dribbling. Thus the pathogenic processes have not been worked out and settled.

Dr. Edward Preble, who does my research work into medical literature, contributes the following case from memory. It is to be noted that the woman may have been somewhat demented: "The patient in my case was a woman whose age I think was fifty-four, single, retired school teacher. Operation was amputation of the breast for ulcerated scirrhous cancer which did not require much time—no clearing out of axilla, etc. The nurses were not allowed to use the catheter at that time. The woman was naturally apathetic and quite indifferent to exposure. Would make no attempt to cover herself although well able. Dr. William Warren Greene, the famous surgeon who operated, told me she looked like a patient with beginning dementia. I don't recall whether I used the catheter as a matter of routine before there were any symptoms of retention. I think not, for surgeons were afraid of the catheter habit if I remember rightly. There seemed no reason to accuse the patient of any hidden desire to have the genitals handled. This patient I am sure died not long after of recurrence or metastasis. The water had to be drawn during the day and for several nights running I was also routed out. I think there was not much urine on these occasions; if there had been I should have thought her within her rights in rousing me. I do not remember how the case turned out in respect to retention. Her sister reported me to the staff because I seemed unwilling to get up; probably one of the other doctors looked out for her as there were three on duty at the time."

Thus far I have not found the least trace of a case like my own. I see no reason why fear of the catheter or other emotional affect may not cause a spasm of the sphincter with spastic retention.

Dr. Bierhoff reported a case of hysterical retention in a young woman (1). This case is nothing like mine but there is a quotation from Frank von Hochwart, the neurologist, who in eighteen years' practice had seen but four cases of hysterical retention. Bierhoff's patient was an onanist. Jellinek (2) reports a case of retention in a hysterical soldier (traumatic neurosis). This patient believed that he had succeeded in evacuating his bladder by an extemporized roll of paper. What really happened may have been relaxation of the spastically contracted sphincter through mental impression. The cystoscope, however, showed hemorrhagic cystitis and trabeculated bladder, throwing some doubt on the neurotic nature of the case. Jellinek further thinks that the hemorrhage into the bladder may have produced the retention and not any neurosis. He thus reverses his own judgment.

In an extensive paper by Rost (3) on retention without stricture not the slightest suggestion is found of cases similar to mine. Rost is very sceptical over neurotic cases—does not deny them, but thinks all diagnostic resources have not been exhausted in many cases classified as neuroses.

La Roque (4), writing on spasmodic hysterical retention of urine, reports the following case:

Case.—Female, aged twenty, single, hysterical for four or five years past. There were no evidences of nymphomania. She had gone through operations for appendicitis and later phantom pregnancy. The last experience was not explained in full. After each of these operations she had retention of urine, the first time for two weeks and the second not so long. Later she had a fall which was not at all severe but which threw her into a hysterical condition, exhibiting vomiting, colic, hysterical stupor and retention of urine. She had been catheterized several times daily with some irrigation of the bladder for a period not stated. At this juncture I saw her. She presented a slight catheter cystitis with redness of the vesical mucosa. The urine contained a little pus. I filled the bladder with weak permanganate solution and then told her to expel it, which she was unable to do. I then gave her a high colonic enema and sent her to the toilet where the colon and bladder were emptied simultaneously. I told her never to allow herself to be catheterized again. If retention should supervene she was to take an enema. The author has repeatedly seen spasmodic nonhysterical retention after operations for piles. In these cases enemas give relief.

It seemed probable that something might be found concealed in the literature of spasmodic stricture, but the surprising discovery was that there was no special literature on that subject. It seems strange that so many write papers on socalled organic stricture, yet no one has any real contribution on the functional. In papers on retention without stricture there is no report of any positive cases.

Cecil, of Los Angeles, has covered the subject (5). He mentions irritation of the posterior urethra in connection with retention, but does not mention the use of instruments as a possible cause. By way of quasicomparison he mentions the spasmodic retention of esophageal sounds in catheterizing the esophagus, but apparently this is not known to occur in urethral sounding. If it did occur, one could understand how retention might come about. J. Cohn has covered the same subject (6). He has had every opportunity to mention retention due to the catheter but is silent. E. Garceau (7) has published a paper in which women alone were considered. Before he examined his forty-three cases he believed that the catheter did at times sin in this respect, but his studies showed that in all cases irritability existed before the catheterization. H. Lett has covered the entire subject of retention (8). He tabulates all the known causes, naming quite a number, and nothing like the catheter is included. He mentions spasmodic stricture as a cause of retention and cites the influence of emotional causes in its production. Rocher and Müller (9) cover the subject of retention without stricture, quoting two personal cases, one in a man perfectly sound but extremely nervous. The retention was found to be due to spasmodic stricture, but the causation remained a mystery.

An article by Guyon (10) has a remote value. Guyon's second case only is at all pertinent. This patient was at the hospital but a few days and evidently left suddenly without the approval of the staff. He was thirty-six years of age. Owing to his premature departure there was no opportunity to use the manometer to measure the strength of the bladder wall. The history, however, presented points of interest. He had for many years complained of various neurasthenic symptoms but only for about ten months had he begun to suffer from urinary troubles which appeared when his neurasthenic symptoms were at the peak of intensity. The suffering was at times excessive and then in order to void urine he had to squat and bear down and at the same time compress his perineum strongly with the hand, at the same time leaning forwards. This kind of behavior always suggests spinal mischief of some kind and Dr. Polsillon, a neurologist, was called in. He, along with Guyon, was able to exclude spinal trouble of any sort. A most careful examination by Guyon failed to locate any urinary anomaly. The membranous portion was only slightly more resistant than normal, the calibre of the urethra quite free, and the prostate normal for the man's age. The bladder, examined with a metal explorer, was barely sensitive and could be freely distended. It could be emptied only imperfectly—slowly and without propulsion. While as stated the manometer was not used, Guyon is certain that the wall of the bladder was enfeebled. The neurasthenic symptoms, aside from severe headaches, often persistent, consisted chiefly of physical fatigue after slight exertion, which would at times compel him to lie abed next day, with extreme mental depression and boredom. He was indifferent as to his disease.

The works of some of the old masters of urology, like Guyon, lead to nothing to the point. I do not find anything, even a catheter habit. The admonition was considered sound to avoid promiscuous catheterization in women lest through suggestion they become unable to void spontaneously. At a later interval came the teaching about concealed onanism, when the medical man was warned that female retention might be feigned to obtain the manipulation. Even this is not mentioned by systematic writers. There is nothing about catheter fear, but there is doubtless such an impression, so that many individuals wait until the last moment before having their water drawn. An unconscious fear might possibly cause reaction like vaginismus.

There is a small literature on hysterical ischuria, which is, of course, not retention but partial suppression. It has nothing in common with hysterical retention although might be readily confused with it and the two have to be differentiated. Frew (11), who reports a case of this, at first looked upon it as one of retention. The subject was notoriously hysterical and he spoke of aversion to beginning the use of the catheter on such a patient. It turned out to be ischuria.

SUMMARY.

There seems to be and there should be a cautious doubt as to what weight shall be attached to such procedures as catheterization and to the psychoneurotic status of the subject. Some men reject the idea of hysterical or neurotic retention and write as if they thought they had been imposed upon by the patients.

The question is at once suggested, "How can the skeptical medical reader be convinced that passage of the catheter caused the retention neurosis!" There is no moral doubt of course in my case. In the strict sense the experience would have to be repeated in the same subject. The diagnosis of psychogenic retention always arouses a faction to dispute the use of the term. Its possible occurrence in general is not denied, but the individual case report is criticized. If the psychogenic nature is conceded, with so many inhibitions possible in theory, how can it be shown that passage of the instrument was at fault? The silence of the profession may indicate a disinclination to attribute retention to the catheter. The number of motivations and inhibitions which might enter into the psychology of such cases is large. A neurologist would place some of the responsibility on other factors.

Yet here is a girl whose impressions were so definitely and immediately productive that she began in a couple of days to imitate epileptiform seizures, borrowing even the aura from a neighboring patient. It is very probable that the impression of not being able to urinate after operation followed by the impression of relief after passing the catheter made the latter temporarily a fixed idea to her. The facts and course of the case seem to justify reporting it and comparing it with allied cases in literature.

Since this paper was completed, the following incidents have occurred and should be included in the report for the sake of completeness:

After this patient had been away from the hospital for a long time letters from the social service department and myself have remained unanswered, either by letter or call. During my vacation in October, 1922, she made one visit to the clinic and then disappeared again. Finally on December 20th I sent the social service nurse to her last address. The result of this visit is that the girl is calling twice a day at a nearby hospital for catheterization. It seems then that the fears expressed early in this paper, about the conduct of the family as to the whims of the patient, have been fully realized. The hospital at which she reported made no inquiry into what I had accomplished. If this inquiry had been made, it is probable that the same plan of treatment following immediately on mine, because concurred in by other doctors, would have convinced and thus cured the patient. The general attitude of the hospital in question can not be described as one of the highest social service relation.

Röntgen Ray and Radium Therapy of Hypertrophied Prostates

By HERMAN B. PHILIPS, M.D.,
New York.

A survey of the records of twenty-five personally treated hypertrophied prostates, representing all types and stages of prostatic urinary obstruction, forces to my mind the inevitable conclusion that this condition fits into the constantly enlarging group of conditions treated effectively by radiation, and therefore, should no longer be considered absolutely surgical. I lay no claim to originality in the method of treatment, although my technic differs somewhat from other methods described, and my conclusions coincide in some respects with those of other operators, previously reported. However, if the patients are to be considered first and always, the following should be considered an earnest plea in their behalf.

The subject of prostatic hypertrophy is of all absorbing interest, occurring as it does late in the prime of life, with no definite established etiology for its basic pathology. Niemeyer's study of thirty-five cases has convinced him that prostatic hypertrophy is a compensatory hyperplasia on the soil of senile involution (1). It is quite generally conceded, however, that prostatic hypertrophy is the result of chronic inflammatory changes. In my opinion, it is highly probable that the abnormal involution of the gland, at the close of the sexual life of the patient, is contributed to by long continued irregularities in sexual habits. The histories of the majority of the patients in my series showed that interrupted coitus had been practised for several decades and in not a few cases masturbation had been practised regularly over long periods.

The types of cases treated must of necessity be grouped, clinically, according to the character and severity of the symptoms and to the physical examination of the prostates, as determined by x ray examination, digital examination through the rectum and by cystoscopic examination. A pathological classification of the prostates treated was of course impossible, owing to the uniform and fairly rapid termination to complete and so far permanent symptomatic cures, and the consequent lack of pathological specimens. The great majority of the prostates were of the large, soft, elastic type with no irregularities in surface or contour, representing the glandular type of hypertrophy. There were a few of the smaller, hard, fibrous type, these being in the minority. All degrees of prostatic obstruction were represented in the group, and as is usual in this condition, most of them were complicated by cystitis. Three of the patients had been living absolute catheter lives from several weeks to two years. Varying amounts of residual urine were present in all the patients who were catheterized. All the patients had not responded to the usual methods of medical treatment (in contradistinction to prostatectomy) and twenty per cent. were such poor operative risks as to be condemned to catheter lives for the rest of their miserable days.

The technic, which was planned and followed with few variations from the first case, was as follows: Four areas measuring approximately three inches square are marked off on the lower portion of the abdomen and over each groin, centreing about the symphysis pubis, and four more areas posteriorly, over the region of the tip of the coccyx, all conveniently arranged for crossfire radiation of the prostate gland. Each area is treated successively with seventy-five milliampere minutes, nine inch back up, twelve inch distance, through four millimetres aluminum. When this is concluded, an intrarectal application of one to two hundred milligram hours of radium through brass and rubber is given, crossfiring on the prostate gland. About two weeks' time is consumed in the giving of this round of treatments, followed by two weeks of rest. Three rounds of treatments, as outlined above, suffice to produce sufficient involution of the gland to accomplish complete symptomatic relief, so that practically in every case the patient is completely relieved of obstructive symptoms at the end of three months. However, it is not necessary to wait this long for definite improvement, for in the uncomplicated cases improvement is noted in three or four weeks' time, with alleviation of most of the distressing symptoms, and by the end of the second series of treatments the patients are almost all symptom free, many sleeping through undisturbed nights and no longer conscious of having urinary bladders. To quote one enthusiastic exsufferer, "I am as good as a youngster again." In the case of three patients, who were very greatly debilitated, practically bedridden, and therefore could not come for x ray treatments, radium packs of three hundred milligram hours through brass and rubber and one and a half inches of toweling, were substituted for each x ray exposure, in the technic outlined above.

The treatment of existing complications in the more serious of the cases was not discontinued or lessened until there was considerable diminution in the obstructive symptoms, which usually took place after the second round of treatments. The usual treatment for cystitis, vesical tenesmus, etc., was carried out here as elsewhere, until with the establishment of better drainage they were gradually disposed of. No amount of detailed exposition of the advantages of this method of treatment could be as convincing as a few case histories which, in order to be entirely free from even a suggestion of coloring from my enthusiasm, are quoted verbatim from the records of referring physicians.

Case I.—E. S., aged eighty-six years, was referred by Dr. H. Adler, who had been called at 3 a. m., April 27, 1921, to see the patient for sudden syncope. He found him very pale with bradycardia (pulse 48), and a hypertrophied and dilated heart; blood pressure, 180-120. He administered atropine hypodermically which gave relief. The patient complained of frequency of urination, voiding small amounts of from one to two ounces every half hour to an hour. The prostate was the size of a small grapefruit and moderately firm. The cardiac condition improved gradually, and by May 2d the pulse rate was 66 a minute. On May 3d a sudden urinary retention developed, for which catheterization became necessary. The patient then had to be catheterized about five times daily. Operation was advised against on account of his cardiac condition, and he was referred for x ray therapy, which was started on May 6th. By May 17th he was again able to void spontaneously, and the prostate was found to be slightly reduced in size and firmer. On account of cystitis, catheterizations and irrigations were continued daily, then semiweekly until the end of June. The residual urine, at first more than an ounce, amounted to only a few drops when the treatments were discontinued. During this time and subsequently the patient had a number of attacks of bradycardia and syncope.

In November, 1921, there was a recurrence of the acute retention. The x ray treatments were again instituted, with similar but quicker results than in the first attack. In March, 1922, there was a third attack of urinary retention. This time the patient was treated with radium, after which the prostate diminished considerably in size. Examination towards the end of May, 1922, showed the prostate considerably smaller and firmer, and no residual urine in the bladder. Although seen a number of times during the past eight months for the cardiac condition, he has not had any complaints nor symptoms referable to prostate or bladder.

Case II.—S. R., aged sixty-four years, was referred by Dr. I. Ritzfeld, who was called in an emergency in the summer of 1922, and on arrival found the patient in agony as a result of acute urinary retention. "I catheterized him, which gave him temporary relief. On questioning him, I learned that he had had similar trouble on previous occasions. He told me that it was necessary for him to void his urine as often as fifteen times a night, and that he found it almost impossible to attend social affairs, as a result of the constant desire to urinate. Upon further questioning, I found that he had been losing in weight, had become irritable, suffered from insomnia, and loss of appetite. I prescribed urotropin, ordered a specimen of urine examined, and advised hot stupes over the lower abdomen. I further advised that this matter be taken up with the patient's family physician and advised that he try a course of x ray treatments. I saw him a few times soon after and then referred him to Dr. Philips for radiation treatment.

"Since having been under Dr. Philips's care, my later report showed that there had been an unquestionable improvement in his general health, along with marked improvement in his urinary symptoms. The urinary frequency and irritation had disappeared, increased amounts of urine were voided at a time, and examination of the prostate showed considerable diminution in its size. The man was able to attend to his business and social affairs, had lost his wan and anxious expression, and had gained in weight. His nocturnal frequency had disappeared and he frequently slept throughout the entire night without disturbance."

CONCLUSIONS.

Analysis of the series of cases warranted the following conclusions:

1. The quickest results were secured in those cases which had the slightest obstructive symptoms, with the fewest complications, and for these reasons cases should be referred for radiation as early as possible, before obstruction, cystitis, impaired kidney function, etc., have definitely established themselves.
2. In the more severe cases, the supportive treatment should not be withdrawn until there is considerable improvement in the drainage of the bladder.
3. Although no uniform considerable reduction was noted in the size of the prostate glands, nevertheless all the patients were completely relieved of obstructive symptoms, in from one to three months' time, depending on the severity of the complications.
4. Recurrence of the obstructive symptoms has not occurred in any of the series, which includes two three year cures.

It is of the utmost importance that malignant cases should be excluded from a course of treatment such as that outlined above, for unquestionably the effect would be stimulating to the growth. Where malignancy is suspected, which should always be the case when continued bleeding is present, or when there are any irregularities in the contour of the gland, cystoscopy should be performed, if feasible, to aid in the exact determination of the condition. It is highly gratifying to remember that cancer rarely begins in a hypertrophied prostate, and that less than one per cent. of hypertrophied prostates are malignant (2).

The presence of vesical calculi, in my opinion, is no contraindication to radiation as the method of choice, in the treatment of hypertrophied prostates. Cystotomy with the removal of the calculi is practically a minor surgical procedure, free from the usual risks of a major operation, and in no way compares in severity with enucleation of the gland. The fact that the first stage of prostatectomy has been done to accomplish the removal of vesical calculi is a poor argument to warrant the following surgical procedure, in view of what can be accomplished painlessly and without risks by radiation. On the contrary, the presence of the cystotomy wound will facilitate and hasten recovery by affording direct access to the bladder for treating the complicating cystitis, and for direct application of radium to the bladder surface of the prostate gland.

In an attempt to establish the actual cause of the relief of symptoms, an original investigation was carried out as follows: The testicles of three of the patients were subjected to sterilizing doses of radium and x ray, the scrotum of each patient being delivered through a fenestrated lead sheet, which afforded effective protection to the prostate and bladder from the rays. These patients were observed for two months without any further treatments. No appreciable change in their condition as regards the bladder or prostate was noticeable. Inasmuch as the treatments could be deferred no longer, on account of threatened discontinuance of cooperation on the part of these patients, they were then subjected to the routine course of treatments described above, with the usual results.

The opposite procedure was now carried out with three other patients, i. e., the testicles were protected with heavy lead sheeting from any possible scattered as well as direct radiation. They were then exposed to the routine course of therapy described above. No appreciable difference in the results secured in these three cases was noticeable, when compared with those cases in which the testicles were not protected. The results of these experiments forced the conclusion to my mind that the relief of prostatic obstruction was the direct result of radiation of the prostate gland and the bladder, in the former by a destruction and absorption of the hypertrophied adenomatous structures, and in the latter by an intense stimulation of the bladder and mucosa and musculature.

These experiments were stimulated by the obsolete operations of castration and vasectomy of Chetwood (3) and Harrison (4) and more recently the reports of Steinach (5), Haberer (6), and Benjamin (7) of vasoligation for the relief of hypertrophied prostate glands, and in addition, by the great similarity between fibroid uteri and hypertrophied prostates. With respect to the former, in the relief of prostatic hypertrophy by radiation castration was not actually anticipated, because of the uniform action of radiation on the entire testicle, as contrasted with the selective action of vasoligation affirmed by these investigators. The comparison between fibroid uteri and hypertrophied prostates deserves more than passing comment. Embryologically, the homologue of the prostate in the female comprises a group of glands in the urethra including Skene's gland, Bartholin's glands, and a few minor vestibular glands. However, the organ which is the actual counterpart in the female of a hypertrophied prostate is a fibroid uterus, not only histologically but also because of some probable similarity in their respective relationships to testicle and ovary.

Here, diverting still farther, a pathological report of a fibroid uterus might well apply to a histological description of a hypertrophied prostate. Glandular proliferation, fibrosis and the production of multiple small spheroidal tumors, will be found in the individual description of both conditions. These experiments, in view of the possibilities of individual and separate radiation of testicle and prostate, as contrasted with the inseparable radiation of uterus and ovary, due to the differences in their respective anatomical relationships, may throw some light on the existing controversy between the French and German schools of therapy, as regards their respective explanations of the reduction by radiation of myomatous tissue. According to the French explanations, shrinkage of these tumors is the result of the direct action of the rays on the fibromyomata, whereas the Germans maintain that the effect is a secondary one and that the rays are efficacious only through their action on the ovaries (8). Without doubt, if the logical comparison is at all permissible, the experiments described above substantiate the French theories.

The question naturally arises at this point, why has the radiation of fibroid uteri so completely outdistanced that of hypertrophied prostates, when they are identical in so many characteristics? How can one account for this discrepancy, when on the one hand radiation therapy of fibroid uteri has completely supplanted operation, except where some definite accepted contraindication exists, such as extreme youth, pedunculated tumors, the presence of infection in the pelvis, etc., whereas in hypertrophied prostate glands comparatively few of our professional brethren are even aware of this nonoperative means of alleviation of the condition? I feel that the members of my specialty are at fault for not investigating this subject before this time, and acquainting the profession at large with their results and teaching them that probably as much can be expected from the radiation of hypertrophied prostates, painlessly and without operative risks, as from the parallel condition of the fibroid uterus.

It is indeed surprising, considering the general prevalence of prostatic hypertrophy, and the advantages of the radiation form of treatment, that so little has appeared in medical literature on this subject. The first record of any case treated, that I have been able to find, was published in the year 1907 by L. B. Bangs (9). Temporary relief was secured in this case after radiation was directed through the perineum only. All the symptoms recurred. In 1920, reports of röntgen ray therapy of hypertrophied prostate glands were published simultaneously by Haret (10) in France, and Oppenheimer (12) in Germany. It is the opinion of both these investigators that x ray therapy is the logical treatment and relieves symptoms where glandular hypertrophy only is present. Beyond this, both authors are skeptical of beneficial results.

Less than two years ago, S. Stern (10) reported excellent results with x ray radiation exclusively. His technic was the administration of direct radiation to the rectal surface of the prostate gland through the rectum by means of a leaded glass speculum. He supplemented this radiation by crossfiring through the perineum. He reported two five year cures of very severe cases, but called attention to the difficulties encountered in the more severe cases where sacculation and loss of bladder tone interfered with a thoroughly ideal end result.

This brief summary of the results of radiation therapy of hypertrophied prostate glands, even excluding the results in my series, shows unquestionable progress in the results attained. It is my firm opinion that in the near future more extensive and widespread experience with the method and probable improvements in technic will definitely establish radiation as the method of choice in the treatment of this condition.

A brief survey of the surgical aspects of this condition is appropriate before concluding this presentation. Notwithstanding the fact that H. H. Young (11) recently reported a series of 165 consecutive prostatectomies without a death, the facts remain that the mortality in selected cases with operators of wide experience is three to seven per cent., whereas in unselected cases, with less experienced operators, the operative mortality is as high as twenty-six per cent. Additional evidence regarding the gravity of the surgical treatment of this condition is given by the postoperative mortality of seven to nineteen per cent. It must be remembered that not all patients can avail themselves of special urological service where everything is as it should be. The average case is the unfortunate one, which because of complications and urgency is treated in his own community with, as a rule, considerably increased risks.

Mention must also be made of the postoperative complications and sequelæ which require expert attention and skill. Among these, in their order of frequency, are wound infection, pyelonephritis, epididymitis, phlebitis, hemorrhage, cardiac disease, and uremia, any of which gives grave concern to the operator and not infrequently contributes to fatality (16).

Less important among the objectionable features of operative treatment are the discomfort, pain and anxiety, from the disturbing and irritating urinary leakage from the cystotomy wound.

In spite of improved technic and lessened operative mortality in recent years, prostatectomy, with its dangers, complications and sequelæ, remains a serious major operation, and is still undertaken frequently with reluctance as the last rational procedure. The advice of DaCosta given years ago (17) summarizes most effectively the dangers of operative treatment, and in most respects his comments obtain today. "Give palliative measures a reasonable trial; if they fail, operate. Prostatectomy is altogether too grave an operation to be resorted to as a routine treatment for every enlarged prostate. The operation is not to be regarded as a trivial affair, certain to result in a cure. It is a grave procedure, with a considerable mortality, which may be attended by disastrous complications, and from which unfortunate consequences may arise."

In the preceding, the author feels that he has substantiated his introductory remark, that the treatment of hypertrophied prostate should no longer be considered absolutely surgical, and he will add that in his opinion, the routine treatment for this condition should be radiation, and operation reserved for radiation failures, should they occur.

SUMMARY.

1. X ray or radium therapy offers a painless, nonoperative method of reducing hypertrophied prostate glands and relieving prostatic obstruction.

2. The effects of radiation are due to destruction of the adenomatous structures in the glands and to stimulation of the bladder mucosa and musculature.

3. Sterilization of the testicles with radiation produced no appreciable effect on hypertrophied prostate glands.

4. Exclusion of the testicles from direct and scattered radiation in the routine series of treatments caused no appreciable differences in the usual results.

5. Radiation therapy should supplant operation as the method of choice in the routine treatment of hypertrophied prostate glands and operation reserved for radiation failures should they occur.

The author's references will appear in his reprints.

Prostatectomy

By WATERS F. BURROWS, M.D.,
and ELLIOTT C. BURROWS, M.D.,
New York.

Prostatectomy has become a most satisfactory surgical operation, being safe and followed by normal bladder function. The patient with prostatic obstruction, whether the gland is large or small, suffers from urinary retention of a few ounces to sixty or more. He is more or less toxic even with an uninfected bladder, but with the latter condition impairment of health is more pronounced and the kidneys, liver and digestive tract are under added stress. The prostatic patient is under weight and one of the results of prostatectomy is a marked increase of weight and vigor.

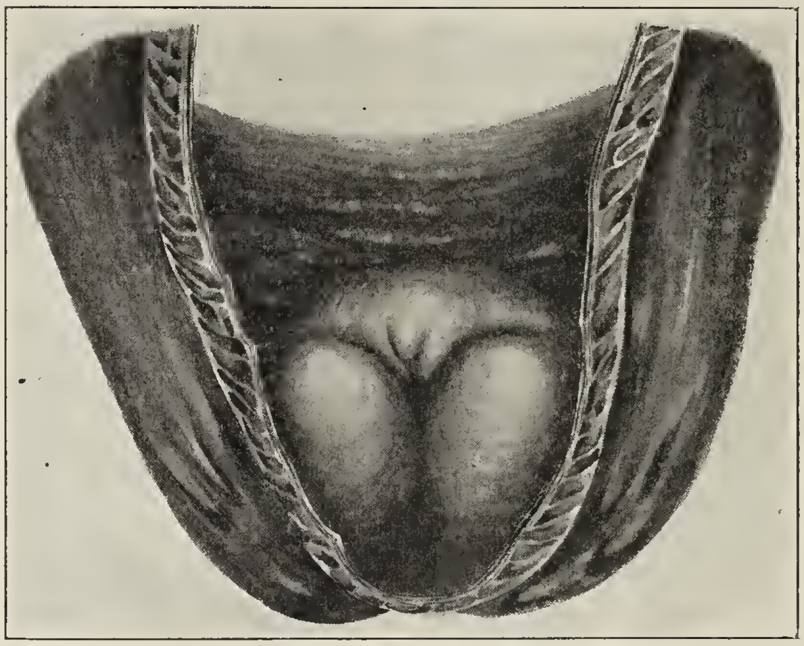

Fig. 1.—Common types of prostatic obstruction. (Anteriorposterior views of lower bladder.) Hypertrophic prostate, raising internal meatus above bladder base.

TECHNIC.

With the improvement in technic little remains to be accomplished in this common operation, and with the avoidance of complications we now urge early prostatectomy. The operation is done under spinal anesthesia and through a suprapubic incision. After retracting the bladder walls and inspecting its interior for the presence or absence of stone, the prostate tumor is completely detached by means of the index finger of the right hand, usually assisted by that of the left within the rectum, the prostate being lifted. The loosened gland is then removed by means of a sponge clamp.

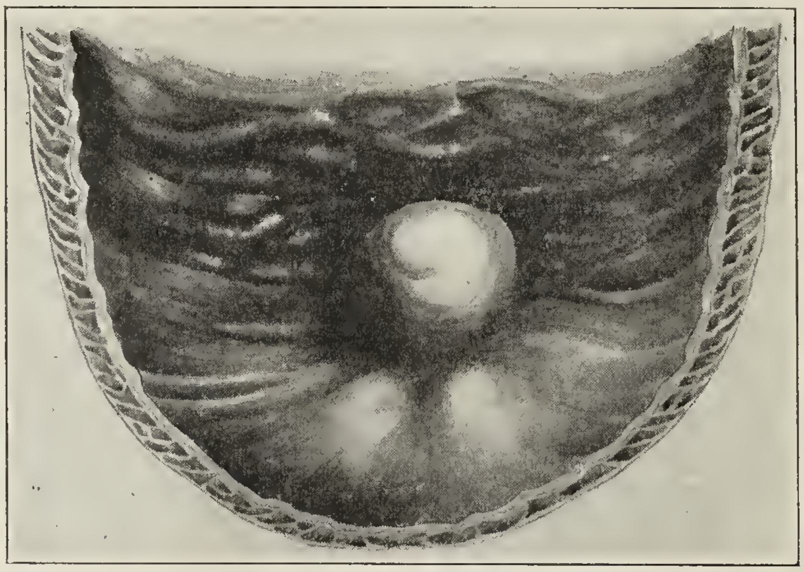

Fig. 2.—Middle lobe hypertrophy forming ball valve obstruction of internal meatus.

AFTERTREATMENT.

The immediate aftertreatment in these cases is now varied from the hitherto usual procedure. Packing of the bladder or the use of special means to exert pressure upon the site freed of the tumor is unnecessary and thus afterdistress and chances of infecting the bladder are obviated. The only step indicated is thorough irrigation with warm boracic acid solution and the reinspection of the bladder to remove any tissue that may have escaped the cleansing irrigation.

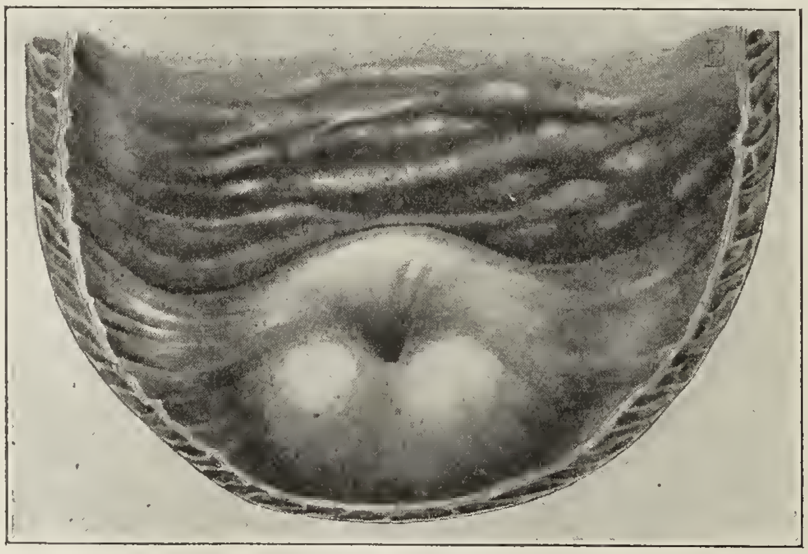

Fig. 3.—Sclerotic prostatic obstruction.

The reason for absence of hemorrhage is twofold—first the spinal anesthesia and secondly the intracapsular enucleation of the enlarged gland. Spinal anesthesia is associated with a moderate drop in blood pressure which persists for an hour or more and does not fully return to the previous registration until the patient is out of bed. Moreover, the shock, associated with ether anesthesia, is absent. The bloodvessel wall therefore contracts immediately and firm clotting occurs normally. Of minor import is the intracapsular enucleation, since in no other way can the gland be properly and cleanly removed. Following the operation a tube for suprapubic drainage is alone indicated.

CONCLUSIONS.

In conclusion we emphasize the importance of removing the obstructing prostate before toxic symptoms occur and kidneys and liver are taxed with products of urinary retention. With favorable conditions the operation is done in one stage, under spinal anesthesia, with no after drainage with the exception of a suprapubic tube which is left in place for one week.

17 East Thirty-eighth Street.

Unsuspected Syphilis*

By LOYD THOMPSON, Ph.B., M.D., F.A.C.P.,
Hot Springs National Park, Ark.

There are three distinct classes of syphilitic patients who apply to the physician: 1. Those with symptoms or lesions which they know to be due to syphilis; 2, those with symptoms or lesions of which they themselves are doubtful, and 3, those with no thought of syphilis in their minds. It is this third class which is probably the most important, as the possibility of their disease being overlooked is very great.

This class of patients may present symptoms or lesions which are obviously syphilitic and a diagnosis may be reached at once. However, the majority of them present themselves to the physician with more or less vague, indefinite symptoms, and a correct understanding of their cases may be most difficult. These patients most frequently apply to the general practitioner, who will often fail to make a correct diagnosis unless he is careful and constantly remembers that syphilis may cause almost any symptom complex.

On the other hand, cases are sometimes observed which are obviously syphilis, and it may be well to mention here some of these cases and point out some of the pitfalls which the physician may encounter if he relies entirely upon the presenting symptoms and does not take into account the whole clinical picture of the case.

A typical chancre of the genital organs, particularly of the male, would present little or no difficulty of diagnosis even if taken by itself. However, a positive diagnosis of syphilitic chancre should never be made of any lesion without an examination for the Spirocheta pallida. In like manner the early adenitis developing in the inguinal region soon after the appearance of the genital lesion, which is usually bilateral, but may be unilateral, is also of little diagnostic value. The early syphilodermata are usually typical and when taken in conjunction with a genital lesion and an adenitis may be considered pathognomonic of syphilis. The same may be said of early mouth lesions.

The congenital syphilitic, the typical weasened, pitiful infant with the hoarse, raucous voice, the snuffles and the bullous syphilodermata cannot be mistaken for anything else. In older children born with the taint of syphilis, developing a deafness, a typical set of Hutchinson's teeth and interstitial keratitis at about the age of puberty, a diagnosis of congenital syphilis is easily made. In fact, the development of these three symptoms known as Hutchinson's triad, is pathognomonic of congenital lues. Between these classes of cases, which we may term as obvious syphilis, and the types which are unsuspected both by the patient and the physician, there are a great number of cases which may be called suspicious syphilis.

In this class belong all genital lesions, and the oft reiterated note of warning in regard to genital lesions is possibly not out of place here. No genital lesion, no matter how trivial or how typical of some other condition, should be passed by without a thorough investigation into the possibility of its being syphilitic. Here the dark field becomes almost the *sine qua non*. In my opinion the staining of smears is almost valueless except in the hands of an expert. However, a recent method of examination, which is full of promise, has been developed by Klauder and Kolmer (1) and amplified by Stern and Rypins (2). This consists of applying the Wassermann test to fluid collected from the lesion. In untreated and uncomplicated syphilitic chancres this is usually not necessary, except in the absence of a dark field apparatus. But in chancres complicated by chancroid, phagadenic chancres, and in those which have been treated by some type of cautery, this method becomes of the greatest value, as a positive is frequently obtained before the blood collected in the usual manner becomes positive. One single negative dark field examination or one single negative Wassermann on the chancre fluid is not enough; at least three or four should be made, and these should be followed by frequent Wassermanns on the blood until all danger of a syphilitic infection is passed.

The inguinal adenitis following a genital lesion, if bilateral, is suspicious, but not at all pathognomonic. Here an aspiration of some of the gland juice and examination by the dark field is often of value. In like manner the later adenitis, particularly the bilateral epitrochlear enlargement, is suggestive of syphilis, and should lead the physician to make a most careful investigation for other evidences of this disease.

It has well been said that the syphilodermata may mimic any known skin lesion: For example, the roseola may often resemble measles, the pustular syphilodermata, the lesions of smallpox, and certain gummata of the skin, epithelioma. It therefore behooves the physician to consider the skin lesions with which he comes in contact and which he thinks are syphilis as possibly something else until he proves them specific.

Periostitis, particularly of the shafts of the long bones, is most suggestive of syphilis, and in cases of dull or severe pain, of tenderness and more or less swelling in one of these bones, and to which no local cause can be ascribed, syphilis must be considered. Aortitis is often mentioned as being caused solely by syphilis. However, this is probably not the case, although a definitely diagnosed aortitis should be looked upon with suspicion until some other etiological factor has been determined. Certain neurological findings, such as increased or absent knee jerks, and pupil abnormalities, are suggestive of syphilis of the central nervous system, but are not pathognomonic and should therefore be thoroughly investigated before a diagnosis is made.

In the realm of congenital lues any one of Hutchinson's triad, Hutchinson's teeth, an interstitial keratitis, or a deafness developing near the age of puberty, is suspicious, but taken alone cannot be definitely assigned to a syphilitic etiology.

---

*Read before the Hot Springs Academy of Medicine, Dec. 7, 1922.

The symptoms and lesions which are due to syphilis and of which the patient is totally unsuspicious as being caused by this disease are legion and it will be possible in this paper to point out merely the most important of them. As a rule most intelligent patients are more or less suspicious of a genital lesion, although many of them often consider such a lesion as a "hair cut," as it is known in the vulgar vernacular.

Extragenital lesions almost never are looked upon by the patient, and comparatively rarely by the physician, it must be confessed, as syphilitic. It should be stressed, however, that any sore which progresses in spite of the ordinary surgical procedures, particularly if situated on the lips, tongue, tonsils, or, especially in physicians and nurses, on the fingers, should be investigated most carefully and syphilis ruled out or found. Chancres of the mucous membrane of the nostrils, of the conjunctivæ and of the nipple are not rare, so lesions of these localities should not be passed by with no thought of lues.

Perhaps enough has been said concerning the syphilodermata, although it may be well to mention the converse of the postulate outlined above, that is, that at least a great number of the skin lesions which are presented to the physician for diagnosis should be looked upon as possibly syphilitic until they are proved to be otherwise.

Of the general symptoms which are often observed in syphilis malaise may be mentioned. This is often quite marked soon after the appearance of the chancre and in cases of extra genital lesions might be most suggestive.

Anorexia is usually more or less marked, especially during the socalled second incubation period and during the active manifestations of the disease. However, during the second incubation period bulimia may exist and should be looked upon with suspicion.

The most important of the general symptoms of syphilis is the fever, and it is also one which is frequently overlooked, and particularly is it true that a fever of unknown etiolgy is rarely considered by the physician as possibly luetic. During the course of the chancre there is usually no deviation of the temperature from normal. In the phagedenic type of chancre, however, there may be a rise of temperature. The early adenitis also is rarely accompanied by fever but in mixed infections, when suppuration takes place, a rise of temperature may be observed.

The socalled syphilitic fever may be divided into two types: 1, essential syphilitic fever, that is, fever directly due to the action of the Spirocheta pallida and their toxins, and 2, symptomatic syphilitic fever. Of the essential type of syphilitic fever there are three varieties: 1, continuous, or typhoidal; 2, intermittent or malarial, and 3, mixed, which resembles the fever of pyogenic origin.

The continuous variety of the essential type of syphilitic fever is most frequently seen during the socalled secondary incubation period, or as an accompaniment of the early cutaneous lesions, the roseolar or early papular syphilodermata. The temperature gradually rises after prodromal symptoms of malaise, anorexia, etc., rarely going above 38.5° C. (101° F.), although in rare instances a temperature of 39.5° C. to 50.5° C. (103° F. to 105° F.) may be attained. When such high temperatures are observed it is usually during the second incubation period and upon the appearance of the syphilodermata the temperature drops to about 39° C. (102° F.) and remains at that period for several days. It has been stated (Fournier) that this variety of syphilitic fever occurs in about twenty per cent. of syphilitics, but I am of the opinion that it occurs much more frequently, possibly in nearly all cases just prior to, or as an accompaniment of, the early syphilodermata.

The second variety of the essential type of syphilitic fever, the intermittent, is usually observed somewhat later in the course of the disease either with other manifestations or in the socalled latent syphilis. It begins with a chill, usually in the evening, or more often simply chilly sensations, as a distinct rigor is rare, and is followed by a comparatively gradual rise in temperature to 39° C. to 40.5° C. (102° F. to 105° F.). The temperature continues for several hours when there is a more or less profuse perspiration and a fall in temperature. This cycle is repeated daily, nearly always beginning in the evening but at a variable period, and may last for several days or even weeks in the absence of specific therapy.

The mixed variety of the essential syphilitic fever also occurs as a rule later in the course of the disease and with or without other symptoms. It usually is ushered in with a more or less severe chill followed by a rise in temperature of 38.5° C. to 39.5° C. (101° F. to 103° F.) or even higher. This is maintained for a day or two, when it may drop to normal or nearly so, only to rise again to its former height or higher.

The symptomatic type of syphilitic fever is the accompaniment of evident involvement of certain structures and organs in the syphilitic process. Thus, it is frequently seen in syphilitic arthritis, iritis, periostitis, etc., in the earlier course of the disease, and later with gummata of the various organs. It is usually a continuous type of fever and as a rule the temperature does not rise to over 39° C. to 39.5° C. (102° F. to 103° F.). It may last for several days or even a week or two in the absence of proper medication.

Of the blood picture in syphilis little need be said except that it is now fairly well recognized that a lymphocytosis is a rather constant finding and should be looked upon with suspicion. Graves (3) has also pointed out that there is often an apparent anemia, that is, a pallor and an anemic look to the countenance away and beyond the blood findings.

Syphilis of the heart is of comparative frequence and certainly when this organ is found to be diseased a luetic etiology should always be considered. Syphilitic myocarditis is more frequent than is involvement of either the endocardium or the pericardium, Warthin (4) demonstrating microscopic lesions characteristic of spirochete localization in all of his postmortems on syphilitics. Brooks (5) found the pericardium involved in fifty-six per cent. of his cases postmortem and the endocardium in seventy-four per cent. Of the latter the aortic value alone was affected in fifteen per cent. and in thirty-four per cent. both the aortic and the mitral valves were involved, while in none was the mitral valve alone the seat of the process.

The symptomatology of syphilis of the heart does not differ as a rule from the symptomatology of cardiac disease due to other causes. Sachs (6) states that in syphilitic aortic insufficiency the left ventricle is not so enlarged as in this condition due to other causes, and therefore the capillary pulse and double sound over the crurales (Duroziez's symptom) are not so marked. Anders (7) has also observed that there is a more decided arrhythmia in cases of syphilitic aortic incompetency than in those of other etiology. It should also be remembered that statistical studies have shown syphilis to be the most frequent cause of aortic insufficiency.

Therefore, the diagnosis will depend largely upon the history, which when negative is of little value, the presence or absence of other manifestations of syphilis, the laboratory evidence and therapeutic tests. It must be understood that the presence of cardiac disease in an individual undoubtedly syphilitic, both clinically and from a laboratory viewpoint, does not prove the heart condition to be due to syphilis. The improvement of the cardiac symptoms under antisyphilitic treatment will, however, be very strong presumptive evidence that such is the case.

Many cases of disease of the various portions of the respiratory system, especially of the larynx and lungs, have been erroneously diagnosed when in truth the etiological factor was the spirocheta pallidum. Chancre of the larynx is most rare, but has been described (8). The syphilomycodermata, particularly the erosive papular lesions, the socalled mucous patches, are of course frequently located on the mucous membrane of the larynx, and when occurring as the only symptom of syphilis are often mistaken for some other condition. Gummata of the larynx have often been diagnosed as tuberculosis or carcinoma.

Syphilis of the lungs is now recognized as a not infrequent pathological entity, and unless the physician be on his guard he will mistake this condition for tuberculosis. In the latter, however, the apex is more frequently involved than in syphilis, the process is more often bilateral, nightsweats are more common and the cachexia is usually more marked. The absence of tubercle bacilli from the sputum over long periods of time or in marked cases will be suggestive of syphilis, and of course the finding of spirochetes would be positive evidence. A positive Wassermann would be strong presumptive evidence of syphilis, while the improvement under antisyphilitic treatment would be almost conclusive. Finally, it must be remembered that pulmonary syphilis and tuberculosis of the lungs not infrequently exist together.

The mouth and pharynx need only be mentioned to point out that syphilitic lesions of these localities are similar to such lesions in the larynx and need the same care in differentiation. Syphilis of the esophagus is a most rare condition, although Wile (9) is of the opinion that it is not so infrequent as the meagre literature on the subject would seem to indicate. The principal condition for which syphilis of the esophagus may be mistaken is carcinoma. The latter, as a rule, occurs later in life than syphilis, is of more rapid development, causes more cachexia, usually is more painful, more frequently provokes emesis and hematemesis and is more common in the lower portion of the esophagus than the upper. The location and extent of the lesion is determined by the x ray, while the Wassermann test is valuable in establishing the presence or absence of syphilis.

As with syphilis of the lungs, so with syphilis of the stomach, we are coming to the realization that it is not rare. Four types of involvement of this viscus are now recognized, namely, acute syphilitic gastritis, chronic syphilitic gastrititis, submucous gummata and ulcerating gummata.

The diagnosis of acute gastritis occurring early in the course of syphilis, as well as the later chronic gastritis, especially in the absence of other manifestations of the disease, may be attended with the utmost difficulty. However, as in any visceropathy, a Wassermann test should be performed, which if positive would indicate antisyphilitic treatment, and improvement of the gastric symptoms would confirm the diagnosis.

Submucous gummata of the stomach, which have not ulcerated, cannot be differentiated, clinically, from other tumors of this viscus. The history of syphilis, or other manifestations of the disease, including a positive Wassermann, would be strongly suggestive. While not distinctive of gummata a röntgenogram would be of the utmost value in locating the tumor in the stomach.

Ulcerating gumma of the stomach may be mistaken for simple ulcer or gastric carcinoma, and in some cases a positive diagnosis cannot be made. The pain of ulcerating gumma is probably not so severe or regular as that observed in simple ulcer and possibly is not so dependent upon the ingestion of food. Hemorrhagé also, while sometimes noted, does not occur as often as in simple ulcer and may not be so severe. Diminution or absence of hydrochloric acid is the rule in syphilis, while in simple ulcer hyperchlorhydria is more frequent.

In gastric carcinoma the development of the condition is more rapid, the hemorrhage is more frequent, emaciation more marked, and pain and vomiting more constant than in syphilis. The gastric analysis is also very similar except that lactic acid is not so frequently found in syphilis as in carcinoma.

It must be said, in conclusion, that the diagnosis of all types of gastric syphilis may not be made during life, although the improvement of the condition under specific therapy would be most significant, and the final test must rest on the postmortem findings, including, of course, the histological picture, and better still the demonstration of spirochetes.

The incidence of syphilis of the intestine is difficult to determine. However, most writers on the subject agree that it is of rare occurrence. Nevertheless, I should like to venture the opinion that it is more frequent than one would be led to suspect in view of the comparatively few references to the subject found in the literature, and if all the cases with symptoms referable to intestinal disease were fully investigated, an appreciable percentage would be found of syphilitic origin.

The pathology of syphilis of the intestine is similar to that of the stomach, that is, four types are observed, an acute and a chronic syphilitic enteritis, submucous gummata and ulcerating gummata.

Acute syphilitic enteritis usually occurs early in the course of the disease when other manifestations of syphilis are marked, so a diagnosis should be easy.

The chronic type is more difficult as it may occur independent of any outward manifestation of the disease. However, if the clinician keeps syphilis constantly in mind errors should be comparatively infrequent.

Submucous gummata, if of sufficient size to be palpated, must be differentiated from tumors of other types and this can only be accomplished by the presence of other symptoms of syphilis, laboratory procedures, and the result of specific therapy.

Ulcerating gummata are to be differentiated from intestinal ulcers of other etiology, from carcinoma, if in the colon, from amebic dysentery, and if in the rectum from tuberculosis. To a large extent this must be done by careful examination for other evidences of syphilis, laboratory procedures and the result of antisyphilitic treatment.

Syphilis usually occurs earlier in life than does carcinoma and the symptoms extend over a longer period of time. In amebic dysentery the finding of the entameba histolytica will be conclusive. Tuberculosis can usually be excluded by the absence of other evidences of the disease both upon clinical examination and by the use of the röntgen ray.

Involvement of the liver is the most frequent of all syphilopathies, so it behooves the physician when dealing with any liver abnormality to consider syphilis as at least a possible etiological factor.

Icterus gravis syphiliticus, the most serious liver condition due to syphilis and which in reality is an acute yellow atrophy, should be distinguished from this condition due to other causes. There is little in the clinical findings by which to differentiate the syphilitic from the nonsyphilitic, except possibly in the former the onset is usually not quite so sudden as in the latter, although the onset may be very sudden in the luetic type. The importance of always having syphilis in mind when making a diagnosis of any visceropathy is probably no better illustrated than in the condition under discussion, for the prognosis of icterus gravis syphiliticus is far from hopeless, while death is always the outcome of acute yellow atrophy due to other etiology.

There is also an early mild jaundice in syphilis which does not differ symptomatically from simple catarrhal jaundice and which is seen in about one half of one per cent. of all cases of syphilis. The importance of not overlooking syphilis in this condition is selfevident. Syphilitic cirrhosis of the liver is also a well recognized condition and must be differentiated from other types of liver cirrhosis.

Diseases of the spleen so rarely cause clinical symptoms, particularly subjective symptoms directly referable to that organ, that its abnormalities are often overlooked. However, the spleen is often found enlarged in the course of a routine physical examination and occasionally pain in the left side due to splenic enlargement may be the chief cause of complaint, so it is well to remember that palpable hypertrophy of this organ occurs in over one third of all cases of early syphilis.

Clinical syphilis of the pancreas is very rare but syphilis of this organ should be thought of in cases of glycosuria, in tumor of the head of the pancreas, especially in those without cachexia, in cases showing fatty stool, in abdominal pain of unknown etiology and in cases of icterus.

Of the endocrine glands the most important in the present study of unsuspected syphilis is probably the thyroid, although syphilis of the thyroid is a most rare condition. In most of the thirty recorded cases there have been no symptoms. However, in the case reported by me (10) in 1917 there was tachycardia, exophthalmia and albuminuria. In cases of Addison's disease the possibility of syphilis of the adrenals should always be thought of, and in glycosuria, giantism, acromegaly and other evident pituitary disorder syphilis of this gland should be considered.

Of the genitourinary organs, aside from the external genitalia of both sexes, the testicle is probably most frequently attacked by syphilis. Warthin (11) found varying degrees of atrophy and fibrosis of the testes in all cases of syphilis in the male which came to the autopsy table at Ann Arbor. The clinical recognition of syphilis of the testicle, however, is less frequent, but in all cases of swelling and tumors of this organ lues should be kept in mind.

Syphilis of the prostate is a rare condition. In 1920 I (12) reported a case and critically reviewed the literature, finding mention of only twenty-four cases purporting to be syphilis of this gland. Of these only twelve could be accepted as undoubted prostatic syphilis. Nevertheless, it seems that tumors of the prostate should be looked upon as possibly luetic until shown to be otherwise.

The comparative frequency of early syphilitic lesions of the cervix has been called to the attention of the profession by Gellhorn and Ehrenfest (13), so erosive and ulcerating lesions of this location should be looked upon as possibly syphilitic. Spirochetes can usually be found in these lesions, and the Wassermann is generally positive.

Cauliflower growths which simulate carcinoma may be gummatous, so the clinician should not be too sure that all such growths are malignant. Microscopic examination of a section of the tumor is the only sure way of making a diagnosis.

Syphilis of the body of the uterus, the Fallopian tubes and the ovaries need only be mentioned to point out that according to Gellhorn and Ehrenfest with the single exception of a gummatous endometritis observed by Hoffmann (14) no authentic cases of involvement of these organs have been reported.

Syphilis must be looked upon as a possible etiological factor in bladder disease, although it is comparatively rarely recognized. In 1919 I (15) reported a personal observation and reviewed the literature, finding mention of only eighty-four cases, of which only fifty-eight could be accepted as authentic. Since that time a few additional cases have been reported (16). There is nothing pathognomonic in the symptoms of vesical syphilis, but cases of hematuria and pollakiuria should be looked upon with suspicion until other etiology than syphilis be proved.

Luetic kidney disease is now a well established clinical fact. A transient albuminuria occurs frequently in the course of syphilis and is usually of little significance. However, if it persists without proper treatment a chronic nephritis may develop.

Acute syphilitic nephritis is a comparatively common condition and quite a number of cases have been reported in recent years. It differs little from acute nephritis due to other causes, and lues should certainly be considered in all cases where other etiology is not obvious. Munk (17) called attention to the presence of lipoids in the urine observed as fine droplets or in packets which are doubly refractive through a Nichols polariscope. These droplets are found more abundantly in the urine of syphilitic nephritis than in that of nonsyphilitics.

Syphilis of the breast, aside from chancre of the nipple and the syphilodermata, is a rare condition. It, however, does occur both as a diffuse swelling and as circumscribed gummata. That mistakes in the diagnosis of tumors of the breast may happen was well illustrated by the case I (18) reported some years ago. This patient, a woman whose husband had had syphilis three years before their marriage, came to me complaining of a lump in the breast, which in spite of a strongly positive Wassermann had been diagnosed as cancer and an operation advised. She was placed upon antiluetic treatment and in six weeks' time the tumor had decreased to half its former size.

The possible etiological relationship to disease of the bones and joints must always be kept in mind, and all cases in which other causes cannot be found be thoroughly investigated.

Syphilis of the nervous system is such a broad subject that it is only possible to touch upon its relationship to the present study. The importance of thinking of syphilis in practically all neurological and psychiatric cases is readily understood when it is remembered that about twenty-five per cent. of nearly four thousand cases admitted to the wards of the New York Neurological Institute were found to be suffering with disease of the nervous system and that had its origin in syphilis (19). Of course the investigation of any neurological problem, when a syphilitic etiology is suspected, is not complete without a thorough examination of the spinal fluid.

Diseases of the eye constitute many important problems in diagnosis and syphilis as an etiologic factor must often be considered. According to various authorities iritis occurs in from three to six per cent. of all syphilitics and constitutes from twenty-five to seventy-five per cent. of all cases of iritis.

Alexander (20) states that in eight per cent. of all syphilitics retinitis develops, although most authorities consider it less frequent. Syphilis of the other portions of the eye is more rare but should not be overlooked.

The object of the examination of a patient is diagnosis, to determine whether or not a pathological condition exists and if so, to determine its nature, and he who leaves a stone unturned is remiss in his duty. Therefore the plea is made that all examinations be so conducted that the existence of syphilis will never be overlooked.

In conclusion, may I offer the following epigram: Let syphilis be the lodestone of your diagnosis, the polar star of your suspicions, for this ubiquitous disease may mimic any known malady, may attack the prince and the pauper alike, and may invade any tissue or organ of the body.

Results in the Treatment of Syphilis

By FIELDING LEWIS TAYLOR, M.A., M.D.,

New York.

Having been impressed by the inadequacy of many of the reports of cures of syphilis, dependent as they are on one or two negative Wassermann reactions obtained after too brief a period, I have gone over all the cases treated in the Department of Syphilology of the New York Hospital between January 1, 1915, and January 1, 1922, a total of 1,676 cases, and selected those that have been under observation for two or more years. From these I have omitted chronic cases giving distinct proof of involvement of the nervous system, whether the diagnosis was based on physical signs, on an examination of the spinal fluid, or on both. Such cases are in a class apart, as they usually have to be treated intraspinously. I say chronic cases of involvement of the nervous system advisedly, for early involvement of the nervous system, from which the patient makes a complete recovery, is rather frequent—the socalled parasyphilides are the result of smouldering syphilis in the central nervous system which has existed from early in the infection.

Fordyce says that twenty-five per cent. of his cases of secondary syphilis show positive spinal fluids (1). As only about ten per cent. of all cases show clinical evidence of involvement of the nervous system, it would seem that in some cases of early nervous syphilis recovery takes place spontaneously or the disease remains quiescent. This is known to be true from direct observation in individual instances. It is to be remembered in regard to Fordyce's statistics, however, that patients suspected of having central nervous involvement, are especially apt to be referred to his clinic by other physicians. On the whole our results, figured in terms of permanently negative Wassermann reactions, are rather disappointing, but it is to be remembered that we are treating sick people and not fighting blood reactions entirely. Most patients for all practical purposes except propagation of the species are cured. It is difficult to say surely what patients are so far cured as to be able to marry with safety but that the sum of human misery is diminished and the spread of the disease lessened is beyond dispute.

What constitutes a cure? Is one negative Wassermann proof of cure? It is proof of nothing at all. On the contrary it is often a distinct disadvantage, in that it is likely to be given undue weight by both patient and physician. While repeated negative reactions obtained over a considerable period are some indication that the disease is greatly limited or perhaps eradicated, this circumstance is not to be regarded as absolute proof that particular individual is free to marry safe from the fear of begetting syphilitic offspring. While a negative spinal fluid is a further indication of the probability of cure and one of great value, it is not absolute proof, as I can cite cases to show that a relapse occurred after a considerable period as indicated by recurrent positive reactions in the blood, when the spinal fluid was negative. That many patients do marry and their consorts remain healthy, or, if they do become infected, do not pass on the disease to their children, is proved by the serological and physical findings in scores of adults and children in this clinic. By interdicting marriage to all syphilitics many useful and healthy members will be lost to society; yet it would seem that in the present state of our knowledge it is the only safe advice to give, if we would approximate elimination of this scourage.

The preparation of the accompanying tables was accomplished with the assistance of the late Dr. Walter Reynolds. They required an amount of work altogether out of proportion to the information obtained, and yet the findings are not devoid of significance. The results in secondary cases are encouraging while those in tertiary are rather more promising than I had expected to find. Congenital cases are the most difficult to influence serologically, as a glance at the tables will show. Among tertiary cases, omitting parasyphilis from our present discussion, those with extensive lesions of the heart and aorta and those with evident involvement of the liver are especially obstinate.

Dr. Newcomer, of the Pennsylvania Hospital, thinks that the length of time a patient is under treatment rather than the size of the doses administered is of importance (2). Professor Irvine, of the University of Minnesota, says that even mediocre treatment, if given over a period of years, will do much for the average case, whereas even the best treatment, if applied for less than six months, can do little (3). These observations have been confirmed by our experience.

A recent paper by Wade H. Brown and Louise Pearce, of the Rockefeller Institute, on the Defensive Reactions of Animals Infected with Spirocheta pallida (4) emphasizes the fact that the defensive mechanisms of the body are directed, on the one hand, to destruction of the parasite, and on the other, to neutralization of its toxic and other harmful effects; that while the lesions are often prevented or repaired entirely, the parasite is never wholly eradicated; that an experimental animal once syphilitic is always so and is liable to relapses which, in general, tend to become less and less frequent. That the severity of subsequent lesions is in inverse ratio to the disturbance at the site of inoculation; that when a rabbit is inoculated with syphilis, one of three phenomena occurs; 1, generalized disease with involvement of any or most tissues; 2, the disease may be circumscribed to the site of inoculation and the adjacent lymph nodes, and 3, that there may be infection without a sign of a lesion at the point of injection of the virus and little or no clinical evidence of the existence of such.

They stress the orderly progression of events in the evolution of the malady, as shown by the original outbreak of symptoms, then quiescence, recrudescence on one or more occasions, and gradual subsidence, never complete elimination of the infection.

Some of these experiments appear to have their analogues in man, as the frequent occurrence of vascular syphilis and the parasyphilides without history of infection go to show. In many of these cases the original sore and following secondaries were so insignificant as to have escaped notice. Severe cutaneous lesions, on the other hand, are less likely to be followed by parasyphilides.

Another paper, which bears on the prognosis and which has attracted much attention as well as adverse criticism, is by Professor Warthin, of the University of Michigan. He states that forty per cent. of his autopsy material presented microscopical evidence of syphilitic infection, as shown by infiltrations of lymphocytes and plasma cells in different instances in pretty much all organs; as the nervous system, the heart, the aorta, the pulmonary artery, the peripheral arteries, pancreas, adrenal, glands, liver, testes, lung, spleen, kidney, genital apparatus, lymph nodes and bone marrow (5).

That the patient had been thoroughly treated and had a negative Wassermann reaction, Warthin considered no guaranty of the eradication of the parasite. He demonstrated the organism in such a large proportion of his cases (seventy-five out of three hundred) as to make the specific syphilitic nature of these lesions certain. While many of them tend to recovery, all are never eradicated. According to this author an individual once infected with syphilis is always thereafter a spirochete carrier, but these organisms may be as harmless as the streptococci of the mouth.

Professor Warthin's findings have been attacked on several grounds, among which the following are to be noted:

1. That it has never been proved that there are not other diseases in human beings caused by spirochetes that become localized. The answer to this is that we are going contrary to our experience in making such an assumption.
2. That having found spirochetes in seventy-five out of three hundred cases where there were small cell infiltrations, he concluded that all the remaining similar lesions were chronic syphilis. It would seem at least probable that many of them were due to other causes.
3. That there is no evidence that these patients received sufficient treatment.

Engman and Eberson (6) found the organisms in the lymph nodes in three out of fourteen cases of latent lues and in two out of seventeen specimens of seminal fluid by inoculation in rabbits. One specimen of semen was from a man who had been infected thirteen years previously and who had been treated with two doses of salvarsan and pills for three years.

Arzt and Kerl (8) found spirochetes in the scar of a chancre of a patient who had been clinically and serologically well for eight years.

The following statistics from Williams (9) of Johns Hopkins University, will answer a question that is often asked, as to the advisability of treating syphilitic mothers rather than producing an abortion: No treatment of the positive mother results in 48.5 per cent. syphilitic infants; inefficient treatment of the positive mother results in 33.2 per cent. syphilitic infants; good treatment of the positive mother results in 6.4 per cent. syphilitic infants.

Here I mention in passing the interesting efforts especially sponsored by Levaditi and Marie to prove that there exist two varieties of treponema, a dermatotropic and a neurotropic. The evidence advanced is striking but, as I can refer to many patients in my clinic that have involvement of the heart and arteries and some that have unmistakable evidence of gumma of the liver who are victims of parasyphilis, it would seem that either the difference in the varieties is not absolute or that some unfortunates are the hosts of both varieties. Different defensive mechanisms in the hosts may be quite as responsible for the ultimate nature of the disease as differences in the varieties of treponema. I refer you again to the rabbits in which the severity of the systemic disease is in inverse proportion to that of the primary lesion with the same culture of treponema. The Utopian era of serotherapy in this disease has not arrived yet. The idea of this possibility is not new and was suggested in part by the fact that defensive substances exist in certain animals. Horses and cattle, for instance, are immune, while rabbits and monkeys usually recover, symptomatically at least, after a comparatively brief period.

Eminent authorities have long recognized that measures directed towards improving the condition of the host tend to limit the ravages of the causative organism, so that tonics and general hygienic measures are important.

Of the two specifics used in treatment of syphilis, arsenicals have a tendency to attack the bloodvessels and liver, while mercurials are especially harmful to the kidneys. Whenever the kidneys are diseased mercury must be given with care. In some patients it causes marked anemia and has to be discontinued. The only contraindications to the use of arsphenamine are degeneration of the liver and dermatitis exfoliativa. If a patient has ever shown evidence of degeneration of the liver as evidenced by jaundice and protracted vomiting after the administration of this drug, it should be given with caution in future. We have regarded dermatitis exfoliativa as an absolute contraindication to the intravenous employment of arsenicals, although the small doses given intraspinously are harmless. Iodide of potash is not spirocheticidal. It tends to cause degeneration and absorption of the small celled infiltrations characteristic of syphilis.

ROUTINE TREATMENT.

Formerly our routine was to give six doses of arsphenamine followed by twenty intramuscular injections of salicylate of mercury. At present we give eight intravenous injections at weekly intervals of arsphenamine or neoarsphenamine followed by ten or twelve injections of mercury. In chronic cases we begin with a dose of arsphenamine or neoarsphenamine of rather small size (0.3 gm. of arsphenamine or 0.45 gm. of neoarsphenamine) and increase gradually to 0.5 of arsphenamine or 0.75 gm. of neoarsphenamine. Only when we are endeavoring to abort the disease in the primary stage do we employ maximum doses in the beginning of treatment and shorter intervals between doses.

Weight, age and sex have a bearing on the size of the dose. Lately we have acquired such confidence in the safety of neoarsphenamine that we are employing larger doses. In latent cases, especially when the nervous system is involved, several injections of mercury should be given before beginning the arsenicals to avoid the Herxheimer reaction. We prefer neoarsphenamine because of the simplicity of technic, the absence of reactions, the low toxicity, and the speed with which it can be given in a clinic.

Two months after the completion of the course of arsphenamine and mercury, we take a Wassermann reaction and whether it is positive or negative repeat the medication just as before. If the next Wassermann reaction is negative after two months, we take another after two months more; if this is negative, we keep the patient under observation and try to get a lumbar puncture. If the Wassermann reaction is positive on the other hand, we begin the course again, and proceed as before.

For brevity in the tables the reports of Wassermann reactions are noted as positive, doubtful and negative. Four plus and three plus are regarded as positive; two plus, one plus and plus minus are regarded as positive when the reaction had previously been positive. Only those cases are regarded as finally negative in these tables that gave two or more negative reactions over an appreciable interval, usually a year or more. N in the column marked Final Result means cured. P means uncured while D— means probably cured, and D+ probably uncured. The term cured is to be taken with reservation and may mean only that the disease is so far controlled that the organism remains relatively inactive and the Wassermann reaction has a tendency to remain negative.

TABLE I.

Stage	Total cases	Cured	Probably cured	Uncured	Probably uncured	Total Percentage Probably cured
Secondary	32	21	3	7	1	75
Tertiary	44	19	6	17	2	56.8
Congenital	15	4	1	10	..	33.3

TABLE II.

Stage of syphilis		Males	Females	Total	Average age	Average duration of observation in months	Average total quantity of arsph. 3 Neo.=2 Ars. in decigrams	Average number of injections. of Arsphenamine	Percentage of probably cured (=N.)
32 Secondary	N...	11	10	21	27	44	46.2	14.3	75
	D...	3	1	4	28	37	66.5	16.8	
	P...	4	3	7	29	40	84	20	
44 Tertiary	N...	7	12	19	33	48	31.2	8.8	56.8
	D...	4	4	8	36	36	46.8	11.8	
	P...	11	6	17	35	41.2	82.1	20.4	
15 Congenital......									33.3
	P. D. N...	6	9	15	11	44.3	25.1	14	

These ninety cases were selected from 1,676 that were treated at this clinic because they had been under observation for some time rather than because they received ideal treatment.

The Surgical Kidney

By S. WILLIAM SCHAPIRA, M.D.,
New York,
Attending Genitourinary Surgeon, Syndenham, People's, and Sea View Hospitals
and JOSEPH WITTENBERG, M.D.,
Brooklyn,
Attending Urologist, Ocean Hill Memorial Hospital and Dispensary

The question when to operate and, what is of equal importance, when not to operate, is always a serious and often a puzzling one. It is true that destruction or removal of even a considerable amount of renal tissue is well tolerated because the normal supply of renal tissue is superabundant—the amount of parenchymatous tissue present in two thirds of a healthy kidney is sufficient to carry on the normal life processes imposed on the kidneys. Still, removal of a kidney leaves but one, and a pathological condition which is of little significance in a person with two kidneys, such as the passage or attempted passage of a renal calculus, becomes of great concern in a patient with a single kidney. Of lesser importance than nephrectomy is the scar tissue which forms after operation on the parenchymatous tissue of the kidney or after decapsulation of the kidney, though this is injurious also and should discourage operation unless the indications for it are clear.

The indications for operation on the kidney are the same as those for operations on other organs, viz., to repair injury from trauma, as rupture of the kidney, to evacuate pus, to remove tumors or large cysts, to remove injurious foreign bodies (calculi and others) and to relieve tension within the organ. Other indications for operation on the kidneys are to remove a tuberculous kidney, to replace a prolapsed organ, for plastic operation on the renal pelvis, etc.; also to overcome anuria, either reflex or direct.

Let us first take up those conditions where indications for operation are overpowering and those in which the contraindications are slight or nil.

Traumatic injury of the kidney.—The wound may open externally or be subcutaneous. An external wound is produced by a stab, a bullet or other missile. It is clear that the walls of large external wounds must be drawn together, that hemorrhage must be stopped, and if the kidney is so injured that urine is discharged externally with the blood the wound must be laid open and the kidney sutured. Drainage must be provided.

Subcutaneous injury to the kidney is produced usually by indirect violence. The patient falls, perhaps on the buttocks, and the kidney is jammed against the lower rib. It may be torn, perhaps into the pelvis; it may be torn entirely across or pulped. In all cases of severe injury to the kidney shock is common. This may be prompt or it may be delayed, in some cases, as long as twenty-four hours; and powerful stimulant may not be administered for fear of increasing the hemorrhage. We must always bear in mind that the same force which has caused injury to the kidney may have injured other organs and structures also.

The symptoms of injury to the kidney, aside from shock, are pain, tumor and hematuria. The pain may be an ache in the loin, or a socalled kidney pain radiating along the ureter with retraction of the testicle of that side. Of course, pain due to accompanying injury of other structures may be present. Tumor depends on the amount of extravasation about the kidney. Hematuria occurs in all cases where the injury is not too far from the renal pelvis; the hematuria, which may be delayed for some time, is continuous or intermittent. Oliguria or anuria is commonly present the first few hours after injury because of excessive irritation of the injured kidney with reflex inhibition of the other kidney; and this is followed by a temporary polyuria. Sepsis followed in some cases (about twelve per cent.) chiefly where instruments, such as catheters have been used. Secondary hemorrhage may follow separation of a slough.

Operative measures should be used only when necessary, viz., to stop hemorrhage, to drain infected areas, and to remove local irritation which reflexly causes anuria.

Prolapsed kidney.—The question of sewing a displaced kidney into the normal position requires more consideration than operation on a wounded kidney for the following reasons: In perhaps the majority of cases of prolapsed or floating kidney no subjective symptoms are present. Since no useful purpose is served by operation on these, nephropexy is out of place. In other patients symptoms of various kinds are found, due directly or indirectly to the nephroptosis. In some, Dietl's crisis occurs. These are attacks of intense pain caused by twisting of the kidney on its pedicle with resulting intense congestion of the organ; these pains are most commonly felt in the epigastrium. Shock is present with the intense pain, and after this pain is alleviated an ache is likely to remain for a few days.

Some patients present symptoms due to pressure of the displaced kidney on neighboring organs. Dilatation of the stomach may be present as a result of pressure on the fixed part of the duodenum, or jaundice may occur from constriction of the bile duct by traction on tissues which cross it.

Still another group of patients show reflex symptoms such as pain along the genitocrural and other nerves, hypochondria, gastrointestinal catarrh, emaciation, and neurasthenic symptoms. Symptoms, aside from those referred to the kidney, which are suggestive of nephroptosis, are disorders of digestion with repeated gastric crises without discernible cause, or attacks of what appear to be renal colic without the passage of a stone or the presence of a pyelonephrosis.

Supporting the kidney by a snugly fitting jersey or an abdominal belt will often give relief. Before deciding on operation in rebellious cases we should take into consideration the fact that in some instances the symptoms are not benefited by it.

To relieve tension.—A condition of the kidney in which operative procedure comes into question is, broadly, to relieve tension within the kidney capsule, as in acute nephritis—that of scarlet fever for instance, and in chronic kidney diseases where the organ is considerably enlarged and its tissues are compressed by the tough capsula propria. In the acute form of nephritis, anuria is a clear indication for decapsulation. The operation here is best done under local anesthesia and the kidney should be handled as little as possible. In the chronic renal conditions mentioned above, decapsulation will relieve tension within the organ and permit better function. In the latter cases where indication for operation is not so urgent, the fibrous tissue which will form, in time, and which will probably be thicker than the original capsula propria, constitutes an objection to the operation. As, however, this fibrous tissue is produced but very slowly, life may be made more comfortable in the meantime, and perhaps prolonged by the operation.

In some cases of what we still diagnose, clinically, as essential hematuria and in which we find, histologically, some form of nephritis, decapsulation may give fair results: where the bleeding is severe and can not be otherwise controlled this must be done.

Tumors of the kidney.—Tumors of the kidney give a clear indication for radical operation. Only about seven per cent. of renal tumors are found to be benign, and these, at least when they are large enough to be palpated, have a tendency to undergo malignant degeneration. The only contraindications for removal of the involved kidney are, 1, when metastasis has already occurred or the growth has spread so that it can no longer be removed; 2, when the second kidney is in such poor condition that it can not sustain life if the other kidney is removed, and 3, when the patient can not stand the shock of the operation or is expected to die shortly of some other irremediable disease. In the absence of contraindications, no other method of treatment should be considered. The prognosis in operation for malignant tumor of the kidney is grave but is improved if the radical intervention is early.

Renal tumors are found, chiefly, in children under five years of age and in adults over forty. In children the growth is sarcoma as a rule; in adults it is most commonly hypernephroma, less frequently cancer or mixed tumor, but as all are of the utmost gravity, no treatment should be considered but radical removal except where the prospect is hopeless for any other reason. The mere presence of the tumor—the irritation of the tissues by it and the pressure it exerts on the kidney structure, produces fibrosis about the tumor and a general chronic interstitial inflammation of that kidney. The second kidney may develop a chronic interstitial process from the irritation by the toxins of the morbid growth as they are eliminated. But these need not be considered in the question of treatment, for the indication for operation is already absolute, unless such intervention is useless because of complications.

Symptomatically we will group renal tumors into, a, those with hematuria; b, those with tumors; c, those which present both hematuria and tumor, and d, those in which the chief symptom is pain.

The principal symptoms of benign growths are produced by the presence of their mass—by their size and weight and the pressure they exert on neighboring organs. The drag of the heavy mass on its attachments or pressure by it on the back causes pain or lameness of the back; varicocele or edema may result from impingement on bloodvessels; and pressure on the gastrointestinal tract is followed, in time, by gastrointestinal disturbances, viz., distress after meals, nausea and vomiting, and constipation perhaps alternating with diarrhea. Blood is found but rarely in the urine. The tumor mass is palpable, and as in time a loss of weight ensues, a differential diagnosis from malignant growth is difficult.

Hematuria.—In adults this is present, sooner or later, in the vast majority of cases (235 of 257, Albarran) and is the first symptom noticed in about seventy per cent. In children it is found in sixteen per cent. of the cases. The hematuria of renal tumors comes and goes spontaneously, without regard to exertion, and at irregular intervals of weeks or months. The hemorrhage is more profuse than that in other kidney conditions, and generally becomes more plentiful and the attacks become more frequent. The amount of blood lost bears no relation to the size of the tumor and the blood is well mixed with the urine. Not infrequently wormlike clots are found; and if these are several inches long they can come from no other place than the ureters or urethra.

Tumor mass.—In adults this is the first symptom noticed in twenty per cent. to twenty-five per cent. of the patients and is found in almost eighty-five per cent. of the advanced cases. In children it is the first symptom found in a third of such patients and, in time, is found in almost every case. While the growth is yet small it is irregular, moves freely with respiration and can be ballotted; when large it forms a mass of considerable size in the loin, with the colon in front of it. In time it becomes fixed by adhesions. The mass may be rounded and smooth or nodular; it may feel firm and, if large, show areas of less resistance.

Pain.—Pain is a symptom, at some time or other, in forty to fifty per cent. of all cases of renal tumor. The pain has been described among the symptoms found with benign tumor. Tension within the tumor by congestion or hemorrhage into it gives a severe ache in the loin. Such an ache, that is affected neither by motion nor by change in the amount of hematuria and that is relieved only temporarily by medication, is characteristic of renal cancer. Neuralgia along various nerves, the intercostals, the sciatic, the spermatic with pain in the groin or testis, of the ovarian plexus with pain in the uterus and ovaries, or along the gastric and splanchic plexus with gastrointestinal pain, is due to involvement of these nerves. Neuralgia may be the first symptom of the tumor. Tenderness occurs with the pain.

Cachexia is usually a late symptom of the malignant growth. In a small number (eight per cent.) of these cases a specific remittent or intermittent fever, or an occasional attack of fever, is present and disappears with the removal of the growth.

Hypernephroma, the usual type of malignant tumor in adults has a chronic course with latent periods.

Tumors originating in the renal pelvis are rare, but growths springing from the kidney often project into the renal pelvis. With a large number of the growths originating at this point, we find calculi within the renal pelvis; it is probable that the local irritation produced by the calculi encourages the development of tumors. These growths are usually of the epithelial type, the great majority of which are simple papilloma and a small minority, epithelioma. The benign growths show a tendency to malignant degeneration and it is sometimes difficult to distinguish between the two even by the microscope.

Tumors which by their location obstruct the ureter, whether they originate in the pelvis, the kidney or the upper part of the ureter, give symptoms similar to those of renal tumor plus those of obstruction to the flow of urine at or near the pelvis, the latter being renal colic with pain in the kidney region and enlargement of the kidney.

Cystoscopy will often show the growth projecting from the ureteral orifice and the ureteral catheter passed to the renal pelvis will usually withdraw bloody urine and may dislodge pieces of the villous growth.

Early and radical surgical intervention is the only form of treatment to be considered here as the simple growths tend to become malignant and the malignant, to recur after removal. If the growth is restricted to the lower part of the ureter, that is removed and the distal end is implanted into the bladder. If the renal pelvis is affected nephrectomy must be done and if the neighboring part of the ureter is also involved the tube is resected as low as possible. In spite of such treatment the prognosis is grave.

Cysts of the kidney sometimes require operative interference. Of the several varieties of cysts found, some may be dismissed with a few words. Polycystic or cystic degeneration of the kidney is a congenital condition in which the organ consists of a mass of cysts of different sizes, from minute to that of a cherry. When the kidneys are not too large to interfere, mechanically, with the birth of the child, the condition gives the symptoms of interstitial nephritis; in a quarter of the cases we also find hematuria; and many complain of a feeling of weight in the loins and show there a tumor, irregularly embossed.

Nephritic cysts differ from the above in that they are small cysts in the urinary tubules, formed above constrictions which are the result of an interstitial nephritis. The cysts are generally found in the cortex and project beneath the kidney capsule. Symptoms of chronic interstitial nephritis are present. In both cystic degeneration and nephritic cysts it is useless to remove a kidney or part of one because there would be a loss of renal tissue which, while not of the best, yet functions to a certain extent and can not well be spared.

The kidney occasionally presents serous cysts which may be as large as the head of a child and require different treatment from the above. These cysts are situated on the surface of the kidney and their removal does away with a harmful or at best a useless mass without destroying parenchymatous renal tissue. We may attempt to differentiate the cyst from a hydronephrosis by passing a ureteral catheter into the renal pelvis. If the eye of the catheter is at the dependent part of the renal pelvis the hydronephrosis will be evacuated and the tumor will disappear. If the eye of the catheter is in some calyx, only a little of the fluid will pass off. A serous cyst has no connection with the pelvis of the kidney and can not be affected by the catheterization.

Hydatid cysts of the kidney give symptoms somewhat similar to those of large serous cysts—symptoms of the mass that is connected with the kidney. Hydatid fremitus is rare. In time the cysts burst, usually into the renal pelvis, sometimes into the gastrointestinal tract or the lungs or into several of these organs. These cysts are distinguished from hydronephrosis in the same way as the large serous cysts, but the exact diagnosis may be made only with the appearance of the daughter cysts in the discharge from the ruptured cyst.

The serous cyst may be removed bodily together with the adjacent kidney tissue, or the redundant cyst wall is cut away, the rest of the surface is cauterized with pure carbolic which is neutralized with alcohol, and the wound drained. For hydatid cysts a nephrotomy with a thorough washing of the cyst wall with tincture of iodine or some other antiseptic solution will often suffice. The washing is repeated daily for several days, the drain is then removed and the wound allowed to heal.

Hydronephrosis is a distention of the kidney pelvis and the adjacent part of the urinary canal by urine that is retained above some obstruction in the canal. The obstruction may be congenital or acquired, complete or incomplete, and its onset may be gradual or sudden. It may be permanently or intermittently closed. Obstruction in or above a ureter causes a unilateral dilatation; with the obstruction below the ureters we may expect a bilateral hydronephrosis.

If the obstruction is sudden and complete the tension within the pelvis is great; the organ becomes intensely congested, and as it stretches but little under the sudden tension the parenchyma atrophies rapidly as a result of the great pressure. If the obstruction is incomplete, some urine is passed, the tension is less and the atrophy of the parenchyma slower; the sac is stretched more gradually but to a much greater extent till it may hold five, six or more gallons of fluid. With intermittent obstruction the results are somewhat similar to those in the incomplete form. Kidney tissue is very resistant and may function to a certain extent when the passage is reopened.

The symptoms vary with the form of the hydronephrosis. When the obstruction is sudden and complete, severe pain is felt at the region of the enlarged and tender kidney. If the obstruction is removed after some hours or days the symptoms are relieved suddenly with a profuse discharge of urine.

In forms which develop more slowly, where the obstruction is incomplete, subjective symptoms may be absent or a dull ache at the costovertebral junction is complained of. In time tumor develops, and this is either constant or intermittent. The tumor present in the chronic form of hydronephrosis is in the loin or, if large enough, extends beyond it; it is smooth, elastic, insensitive and freely movable unless it is so large that it fills the loin.

A closed hydronephrosis is impervious to a ureteral catheter. A partial obstruction may be passed by manipulation; the passage of the catheter is followed by a gush of urine or by hurried drops; and pressure on the mass will accelerate the flow. When the hydronephrosis is emptied the tumor disappears.

Small dilatations of the renal pelvis are detected by pyelography. The cavity is filled gently, through the ureteral catheter, with some solution impervious to the x ray and a röntgen plate made. The fluid must be injected carefully and evacuated as soon as slight pains appear in the loin.

The prognosis of hydronephrosis depends on whether the condition is unilateral or bilateral, on the possibility of removal of the obstruction, on the possibility of repair of the dilatation in the canal so that no dependent pouches will remain in which urine may collect, and on the condition of the kidneys. The treatment depends on the abnormal conditions present. The obstruction must be removed and defects of drainage must be repaired, by plastic operations, if necessary.

We now come to more debatable ground in the field of kidney surgery, renal calculi. There is no question as to the undesirability of carrying about a stone in one's kidney and that the presence of the stone is at best more or less injurious. On the other hand are to be considered the possibility of ridding the patient of the calculi without operation, the possibility of the stone remaining latent in so far as acute symptoms are concerned, and the probable damage which will be done by the retained stone as compared to the damage which must follow operation on the kidney.

The ill effects of the presence of the calculus may be divided into, a, injury to the kidney; b, injury to other organs or tissues; c, dangers resulting from the presence of the calculus in the tissue, and d, disagreeable symptoms.

The irritation produced by the presence of the stone results in a fibrosis which spreads through the kidney to the capsule. When the fibrous tissue contracts the kidney becomes small and granular. The perinephric fat about a calculous kidney often increases in amount and its stroma becomes fibrous; then the fat invades the kidney at the hilum, spreads along the vessels and compresses, destroys and replaces the kidney tissue. These changes are of course slow.

With increasing disability of the calculous kidney, the second kidney undergoes compensatory hypertrophy. A less desirable change that may occur in the second kidney is a chronic interstitial fibrosis due, perhaps, to the same diathesis which produced the stone in the first kidney.

Obstruction of the urinary canal by the calculus will bring on a hydronephrosis. The amount of damage in such a case depends on the completeness and persistence of the obstruction, as was explained above. A single calyx may be obstructed with similar local results. The presence of calculi is undesirable for other reasons. Mechanical injury produced by them weakens the local resistance to infection. As a result pyelitis, pyelonephritis and other conditions set in more readily in a calculous kidney than in a normal one. Again, acute infectious fevers are accompanied by acute congestion of the kidneys. Such a process is more dangerous to organs that are already irritated and otherwise injured by a stone than to normal ones; and the ordinary oliguria so common at the onset of acute infectious diseases may progress to anuria, direct in the calculus kidney and reflex in the other. Such an occurrence is not common, however; autopsy in fatal cases almost always shows there has been severe disease in both kidneys.

Symptoms—The symptom which most urgently brings up the question of operation is pain. A severe attack of renal colic is a disagreeable experience and, if this is frequently repeated, may become almost intolerable. Pain of some kind is present in about seventy per cent. of the patients with renal stone; characteristic renal colic is found in some forty-three per cent.

The pain produced is not in proportion to the size of the calculus; quite the contrary. A large smooth stone or any stone that is immobile may give no pain at all or may be accompanied by a dull ache in a renal pain area—posteriorly at the costovertebral angle and anteriorly at a point an inch and a half below and internal to the tip of the ninth rib. The intense pain of renal colic is due to the passage or attempted passage of a stone through the ureter into the bladder, so a small, jagged stone may give excruciating pain while the calculus that is larger but smooth acts much more gently.

We must always remember that renal colic may be simulated by the pain resulting from any sudden obstruction in the urinary canal to the flow of urine, perhaps by the passage of a blood clot or a mass of debris. The increase of tension in a renal tumor, by hemorrhage into it, may give a similar pain.

The pain of renal colic begins in the loin at a renal pain area, shoots along the ureter to the external abdominal ring and may continue into the testicle of that side or into the point of the penis—in the female into the labia majora; it may be reflected along the sciatic nerve, down the anterior surface of the thigh or across the abdomen. When the pain is intense, symptoms of shock may be present, the abdomen is rigid and the thigh flexed. The urine passed after the colic may be bloodstained and may contain the calculus.

The calculus may be retained in the ureter, perhaps at some dilated point, without stopping the flow of urine and cause pain and tenderness there; if this occurs on the right side, it is at times mistaken for appendicitis.

In considering the advisability of operation for renal calculus, it would be best, perhaps, to begin with those groups of cases in which the indications for operation are imperative and leave the more doubtful for the last.

Calculous anuria demands operative interference unless indeed it is clear the patient will not survive the operation. Operation before the fourth day of anuria shows a mortality of twenty-five per cent., before the fifth day, 30.7 per cent., and before the sixth day 42.1 per cent. Spontaneous recovery occurs in from twenty-one to twenty-eight per cent. of cases, in some instances after ten days or more of anuria, but in none of these is the second kidney disorganized.

The anuria is due to a total obstruction of the flow of urine, whether by simultaneous blocking of both ureters, blocking of a common stem of both ureters or of a single ureter of a fused kidney; or one ureter may be blocked, while the second kidney is incapable or reflexly inhibited. Such inhibition may be partial or complete.

Hematuria is a symptom that is common with renal calculus; but it is not often of any intensity, differing in this from the type of hemorrhage common with renal tumors. In the infrequent cases where the hemorrhage is severe and can not be controlled, surgical intervention is necessary.

Pyuria is a common symptom and occurs where infection complicates the calculus. This will be considered later with renal infection.

Tumor.—Very large calculi, larger than a normal kidney, have been found, where the tissue has been largely destroyed. The discomfort of the weight of the mass may more than counterbalance the value of the little function left that kidney.

Next comes that group of cases in which attacks of severe renal colic are common and frequent. It is known that patients who pass small renal calculi frequently, and in spite of this show no large stone nor group of small calculi by the x ray, continue to pass small stones after operation. Cases of this type are therefore best treated by nonsurgical measures. If with frequent and severe attacks of renal colic, large masses of stone are shown by the x ray, operative interference is more reasonable. We should also take into consideration the fact that uric acid calculi are not shown by the x ray, as a rule.

The group where doubt as to the advisability of operation is greatest is that in which the symptoms are mild or very slight. The patient may feel a slight ache, at more or less infrequent intervals, along the path of the ureter and this disappears on lying down after some hours. In somewhat severer cases a hypodermic injection of morphine with atropine is advisable. In still other cases the patient complains only of a slight ache in the loin.

As already mentioned, objections to the presence of renal calculi even in cases with very mild symptoms are, a, the progressive damage to the renal parenchyma; b, the greater probability of infection of the kidney; c, the increased danger to the patient in case an acute infectious fever develops, and d, the possibility of obstruction by the stone with resulting hydronephrosis.

It seems to us that when symptoms are absent or very mild, the injury that is apt to be done to the renal tissue by the presence of the calculus is no worse than the damage which will be done by the operation. A small stone in the renal pelvis may be removed through an incision in the pelvis without injury to the renal parenchyma; but we may find astonishingly little damage histologically, after such a stone has been retained for years.

It is possible for renal calculus to develop in a patient with acute infectious fever, and the presence of the calculus may add to the seriousness of the disease. On the other hand, in a comparatively small number of all the patients with renal calculi, an acute infectious febrile disease may be expected to develop, and of those patients only a certain proportion are likely to suffer serious renal complications. We must therefore judge the sum of the increased danger which a small percentage of such patients with renal calculi will incur if they are not operated on, and the totality of danger which will attend operation on all patients with renal calculi and with no indication for operation except that under consideration.

Obstruction of the ureter with development of a hydronephrosis can be attended to promptly if it should occur.

For calculus impacted in the ureter, operation need not be rushed. The majority of such calculi—Braasch believes seventy-five per cent.—pass spontaneously if morphine is administered; and many of the others can be made to pass by intraureteral manipulation. Introduction of the ureteral catheter will stimulate contraction of the ureter and help expel the stone. Injection of sterile olive oil through the catheter will both lubricate the canal and stimulate the tube to contract. Two c. c. of a cocaine solution injected at the site of the calculus through the catheter will often enable us to pass the instrument above the stone, and injection of a few c. c. olive oil at that point, together with the anesthesia below the calculus, will facilitate the passage of the stone.

Renal calculi must be diagnosed from all other conditions which may present somewhat similar symptoms, viz., renal tuberculosis, renal tumor, nephroptosis, cystitis, gallstones and appendicitis. Diagnosis of the presence of renal calculi is insufficient. We must also ascertain the number and position of the stones, the presence or absence of renal infection and the functional capacity of both kidneys.

Renal infection gives profuse pyuria and bacteriuria; and urine procured from the individual kidneys will show if either or both kidneys are involved. The capacity of each kidney is estimated by making one or more functional tests.

Unfortunately not all calculi cast shadows on the röntgen plate, for example, uric acid stones. In cases where caseated lymph nodes lie near the ureter, these may be mistaken for calculi impacted in the ureter. X ray plates taken from different angles with an opaque catheter inserted into the ureter will show if the shadows are at the ureter, to either side, in front or behind the tube.

In case the x ray examination gives negative results and the symptoms are suggestive of kidney stone, the following hints will help: In calculus the pains are usually precipitated by jarring or motion; in all other conditions of the kidney with attacks of pain these are apt to appear spontaneously; with calculi the hemorrhage is apt to be scanty and is also brought on by motion; with tumor the hemorrhage is generally profuse, successive attacks become more profuse and come at shorter intervals; in tuberculosis of the kidney hematuria is spontaneous but the blood is scanty except in the rare instances where the ulcerated lesion is on the tip of one of the papillæ which are vascular; with calculi the urine shows excess of salts and no tubercle bacilli while in renal tuberculosis salts are not in excess and tubercle bacilli are found—perhaps only by animal inoculation; in nephroptosis the kidney is found displaced by bimanual examination and if necessary by pyelography.

Treatment.—The treatment for renal calculi may be prophylactic, medical and surgical. To know how to treat this condition properly it is necessary to understand the formation of urinary calculi.

These stones are composed of urinary salts which have been precipitated and are held together, in rather regular layers, by an irreversible colloid, about some nucleus. The nucleus may be any foreign body as a blood clot, a mass of pus, a tip off a broken catheter, or, in children, a crystal of ammonium urate with which the urinary tubules are filled in infancy. The salts most commonly found in urinary calculi are uric acid, calcium oxalate and phosphates.

The salts are derived from the foods ingested and from the metabolism of the body. In fact, the tissues of the body itself will furnish enough material to form large stones when metabolism is disturbed. It is therefore readily seen that change in diet which will diminish the intake of the offending salts is of little value when excessive production of such salts is present because of some metabolic disturbance. Improving the metabolism of the body by keeping the great ureaforming organ, the liver, in good order so that urea will be formed instead of uric acid, and by taking care that sufficient oxygen is supplied for purposes of oxidation, which presupposes good respiratory and circulatory organs and good blood, are of greater importance by far than curtailing or modifying the diet.

Some of the treatment used for urinary calculi is based on the following: The urine holds in solution more of certain salts than is soluble in water. This solvent power is due to various things; for example, earthy phosphates are soluble in acid and precipitate in alkaline urine, uric acid is more soluble in alkaline and precipitates in strongly acid urine, excess of uric acid is kept in solution by the presence of certain colloids, viz., mucine and urochrome, oxalates are found in urines of all reactions but are kept in solution by acid phosphates of sodium and magnesium.

The third requirement in the formation of urinary calculi is an irreversible colloid of which fibrin is a type. This is present after local hemorrhage or suppuration. It is quite likely also present after prolonged irritation of the renal tissues from the passage of irritating urine—urine which persistently contains excess of salts or bacteria.

Calcium oxalate in the urine is found in several forms, the principal one being the octahedral crystal. The dumbbell shaped form is less common and less numerous, but to us this form seems to be of special significance. We find that after dissolving the calcium oxalate crystals (and incidentally dissolving colloids) and reprecipitating them, only octahedral crystals reappear—no dumbbell shaped crystals are reformed; it therefore seems reasonable to assume that the dumbbell shaped crystals already contain colloid matter. In our opinion the presence of these dumbbells in the urine shows that the person who passed that urine is already predisposed to the formation of urinary calculi.

Prophylactic and medical treatment.—It is clear, in view of the mechanism of the formation of urinary calculi, that the digestive apparatus must be kept in good order, that oxygenation must be improved by moderate exercise and plenty of fresh air and by keeping the respiratory and circulatory systems in as good condition as possible. Modifying the diet is of lesser importance because most of the urinary calculi are made up of several salts; still it should be done. Any textbook will give lists of foods whose use is advised and of those to be abstained from.

Regulating the reaction of the urine may be of service in some cases. For example: phosphatic stones, most of which are formed in the bladder, may be modified somewhat, at least, as to the rapidity of their growth, by acidifying the urine. On the other hand, we do not know of any evidence to show that the urine may be acidified in Bowman's capsule. Clinical experience has shown that in general a mildly alkaline urine is a better solvent than a more acid urine; and diluting the urine increases its solvent power by increasing the amount of water passed. As for drugs which are solvents of urinary calculi, we know of none though some are recommended by different writers as having some solvent power.

Gumma of Nasal Septum

By ELLIS M. SCHWARTZ, M.D.,
New York,
Adjunct Surgeon, Ear, Nose and Throat Department, People's Hospital

Patients complaining of chronic obstruction to the breathing through their nasal passages, naturally come for relief to the rhinologist. He will find the cause as being either an hypertrophied turbinate, polyps, a deflected septum, a deflected septum with thickening, or a combination of these causative factors, and he will advise operation.

I am mainly devoting my attention in this article to the septa which show thickening. On examination in such a case, there will be noticed on one side a convexity, while the other side, instead of showing only a concavity will also show a convexity. Such patients have too often been operated upon. If a Wassermann were taken, they would be found to be specific, and if antispecific treatment were instituted, the thickness of the septum would disappear and the patient would be cured without operation. Several such cases have fallen under my observation.

Case I.—Mrs. M. V., aged forty-nine, in September, 1920, came to me with the following complaints: Pain over the nasal region, headaches, inability to breathe through her nose, this latter condition having gradually increased for the past few years; a pussy discharge from the left nostril, and some of the symptoms associated with mouth breathing.

Rhinoscopic examination revealed the septum first thickened on one side, and instead of the concavity usually found on the other side in a case of deviated septum, the second side was also convex. In other words, the septum was thickened, extending into and filling up the nasal cavities on either side. A pussy discharge was seen coming from below the middle turbinate on the left side. I went into her history very carefully and learned that there had been several miscarriages. She also impressed upon me the fact that she had for years suffered from headaches, more of a boring pain over the nasal region. I examined her further and found Argyll Robertson pupils; knee jerks were diminished, Wassermann was four plus. I decided not to operate. Instead the patient was subjected to a thorough course of antisyphilitic treatment. Six months later, there became noticeable a marked improvement in the breathing of the patient. The thickness of the septum was diminished, thus increasing the breathing space. Transillumination showed the left antrum cloudy. X ray also showed involvement of the antrum. I broke away the nasal wall of this sinus.

Case II.—A. L., a young male thirty years of age, came with the following complaints: Almost total obstruction of the nasal passages, lacrymation, and nasal discharge with slight odor. On examination I found a septum as described in Case I. It was thickened, a convexity on either side thus projecting into and occluding the greater part of the nasal cavities. I took a Wassermann of the patient and the report came back four plus. This patient also received a course of antispecific treatment and in the same period as in Case I, also noticed that he could breathe more freely through his nose. On examination, the septum was one half its previous thickness.

Case III.—Mr. J. B., aged forty, was sent to me for operation on a deviated septum. He complained of inability to breathe through the nose, of catching cold easily and of headaches. The same septum was found as in the other cases, namely, a thickened septum, convex on both sides, extending into and obstructing both nasal cavities. On questioning he gave a history of having contracted syphilis years ago. His Wassermann was also positive. This patient was treated as the others; an operation which would have been done unnecessarily was avoided.

CONCLUSIONS.

Syphilis of the nose is not so uncommon as it is believed to be. Just as it affects other organs it affects the nose. A perforation through the septum with no history of an operation, most often speaks for syphilis; of course it may be due to other causes such as constantly picking the nose or to an atrophic condition, or to infection due to diphtheria, or to tuberculosis. The point I wish to emphasize is the importance of diagnosing a case of gumma of the septum before perforation with its attending symptoms comes on. These cases come to you with symptoms of nasal obstruction. If an operation is performed, it is very often followed by a breaking down of the entire septum. If left alone, no operation being performed, and no treatment being instituted, the amount of infiltration of the perichondrium and periosteum may become extensive and marked necrosis may follow, with an inevitable loss of the bony and cartilaginous portion of the septum and in some cases suppuration of the accessory sinuses.

Whenever a case presents itself with a thickened septum convex on both sides, causing nasal obstruction, the history should be gone into very carefully to determine the existence of syphilis. A Wassermann should be taken. No operation should be performed until gumma is ruled out. If found positive, do not operate, but place patient on antisyphilitic treatment, because the prognosis as regards the removal of gummata is good, as fatty degeneration and absorption will take place under antisyphilitic treatment.

221 Second Avenue.

The Intravenous Administration of Iodides*

By FREDERIC J. FARNELL, M.D., F.R.C.P.,
Providence, R. I.

In a previous paper in 1921 (1) I presented a preliminary report upon the administration of iodides intravenously. Since that presentation an effort has been made to isolate definite clinical disease entities in which hypertonic solutions of iodides have produced recognizable results. The experimental work dates back about six years and was first directed toward the treatment of systemic oïdiomycosis, the objective being to place in the body a hypertonic solution of high concentration. For this a ten per cent. solution of sodium iodide was used, boiled for ten minutes, cooled and given immediately by gravity by way of the vein and requiring ten minutes for the entire amount to enter the blood stream. Within my experience, no ill effects have resulted therefrom, probably due to the fact that the solution is made up fresh for each treatment and is boiled ten minutes before being administered. Kendall (2), in his paper on the determination of iodine in connection with the studies of thyroid activity, says, "In the original method it was recommended to use a ten per cent. solution of potassium iodide. All commercial potassium iodide will liberate traces of iodine on long standing in aqueous solution—the solution must be boiled ten minutes as a minimum length of time in order to remove all traces of sulphurous acid." When solutions of sodium iodide, especially those of high concentration, are placed in ampoules and kept over a long period of time, there is a liberation of iodine which increases markedly the acidity of the solution and renders it valueless. Freshly prepared solutions, both before and after boiling, tend toward the alkaline side to methyl red and rosalic acid, as well as to litmus.

In 1919 Weed and McKibben (3) made several interesting observations upon the relation of hypertonic and hypotonic solutions to variations in brain bulk and intracranial pressure. They used as their solutions, distilled water, sodium chloride, sodium sulphate, sodium bicarbonate and glucose. In short, their deductions were that an intravenous injection of a hypotonic solution produced a marked and sustained rise in intracranial pressure and an increase in brain bulk, whereas an intravenous injection of a hypertonic solution produced an initial rise, then an immediate fall which is sustained, and a decrease in brain bulk.

---

*Clinical Material and Observations made in the author's private laboratory.

That these changes are independent of the amount of fluid injected and probably due to the fundamental osmotic effects of the hypertonic solutions might be illustrated by the action of a hypertonic solution of sodium iodide in such disorders as secondary edema in arterial conditions affecting the brain. As an example: A single woman of sixty-six years, a musician by vocation, began in the spring of 1920 to suffer from a cramping of the toes of her right foot. In the fall of 1920 she became aware of a marked tremor of the right arm and an inability to associate the coordinative movements of the fingers of her right hand at the piano. These symptoms increased in severity and in December, 1921, she took to her bed. She gradually became confused, disoriented, had emotional outbursts, apparently lost her memory and reacted abnormally to sensations seen and heard. In March, 1922, the symptom complex was a coarse tremor of the right arm and leg, with muscular spasms and choreoathetoid movements and exaggerated automatic associated movements (when cooperation could be obtained), with emotional outbursts. If she sat up in bed she would double up like a jackknife and undoubling was difficult. There was no evidence of an involvement of the pyramidal system and there was an absence of sensory disturbance. Mentally she was confused, disoriented, with loss of memory for recent past. Her speech was a jargon with perseveration and echolalia. Blood chemistry presented blood sugars 150 mgm. to the 100 c. c.; urea nitrogen, 34.9 mgm. to 100 c. c.; preformed kreatnin nitrogen, 2 mgm. to 100 c. c.; whole blood chlorides, 6.2 gms. to 1,000 c. c. The carbohydrate tolerance tests revealed, 1, 150 mgm.; 2, 250 mgm.; 3, 300 mgm.; 4, 300 mgm.; and 5, 250 mgm. These symptom complexes suggested a localized lesion in or near the striatum with secondary edema. In view of this conclusion four intravenous hypertonic sodium iodide solutions were injected intravenously at intervals of five days, with the result that all the secondary symptoms, confusion, disorientation, speech jargon, illusions of sight and hearing disappeared leaving the residual tremor, choreoathetoid state from which she is still suffering. This seems to illustrate the probable reduction of intracranial pressure and brain bulk, through the medium of a hypertonic sodium iodide solution.

Hart and Steenbock (4) as well as Smith (5) have made excellent observations upon a malady occurring in pigs known as the "hairless pig malady." At first it was thought to be a protein disorder due to a restricted feeding of one or a special type of grain. A correction of this fact, however, did not always correct the disorder. It was later observed that the hairless pigs suffered from a hyperplastic thyroid. This led to the use of potassium iodide in the treatment of the hairless pig with corrective results. The dose was ten grams of potassium iodide to every hundred pounds of feed for the sow.

In lues, a not uncommon symptom is alopecia areata which is in general looked upon as a local affection even to destruction of the hair follicles. The pathology of alopecia areata usually rests with those facts—if it does respond to intensive antispecific treatment it may have been merely an affection—should it not respond in due time, there may be destruction and the condition considered a permanent lesion. Reference is not made in these remarks to the alopecia observed in postinfluenzal or scarlet fever cases which according to Parkon and Jacoby (6) respond immediately to adrenal lipoids even though, in their cases, the thyroid gland was considered enlarged.

In those cases which do not respond to salvarsan intravenously and iodides by mouth, the author recommends a series of intravenous hypertonic solutions of sodium iodide at intervals of five days. Surprising results have been obtained although in none of the cases were there any symptoms of hyperplasia of the thyroid unless one would wish to recognize the neurasthenic or psychasthenic reaction of makeup, which were the types of cases under observation, as indicative of a thyroid disorder.

As in systemic oïdiomycosis where lesions are not infrequently observed in the periosteal lymph nodes and in the bone itself, so in lues affecting the periosteal lymph nodes or the bone such as periostitis of the skull or spinal column and one which does not respond to salvarsan intravenously or iodides by mouth will respond, as in oidiomycosis, to the intravenous injections of a hypertonic solution of sodium iodide.

Why could one not give large doses of iodide possibly with a bland syrup, by mouth, and avoid the more or less selective method via the vein?

Do the results depend upon the high concentration or the intravenous channel of administration?

After a period of observation extending over several years, with sodium iodide in hypertonic solution, the conclusion has been drawn that it is of marked value in systemic oïdiomycosis.

Certain selective cases of arterial disorders in which there is a symptom complex suggestive of cerebral edema, pseudotumor or brain wetting, hypertonic sodium iodide solutions are in order.

In lues, especially in the treatment of alopecia areata and lesions referable to the bone or periosteum or both, appear to respond fairly quickly to hypertonic sodium iodide solutions.

It is the view of the author that the intravenous method is superior to the oral method in the administration of hypertonic solutions of sodium iodide, due to the fact that tissue reaction is undoubtedly more quick and that the salt reaches out into the tissue more rapidly than it could by absorption by way of the gastrointestinal tract.

The Treatment of Gonorrheal Epididymitis with Intravenous Injections of Sodium Iodide

By LOUIS T. WRIGHT, M.D.,
New York.

Epididymitis of gonococcal origin is an extremely painful condition for most patients, and for physicians is at times very difficult to handle in a satisfactory manner without resorting to surgical measures. Any treatment that will relieve pain and tenderness promptly and eliminate the necessity for operation deserves careful consideration. It is, of course, understood that any new treatment should present fewer elements of danger than present day accepted operative procedures. Some evidence is at hand which seems to indicate that intravenous injections of sterile solutions of sodium iodide have a remarkably beneficial effect in these cases.

In 1915, Murata (1) reported that he was successful in the treatment of gonorrheal epididymitis by the intravenous injection of thirty grams of a calcium salt solution. Stern and Ritter (2) were the first to note the effect of intravenous injections of sterile sodium iodide solutions in gonococcal disease of the epididymis. In some of their cases these observers used hot colonic irrigations and ice locally to the scrotum, in addition to their use of sodium iodide intravenously. They noted a rapid subsidence of acute symptoms. The number of cases of epididymitis that they treated with sodium iodide is not stated. Ravich (3) reports excellent results obtained by its use in ninety personal cases and seventy additional cases that he had the opportunity to observe. Many of his patients received, in addition to the sodium iodide, local treatment with guaiacol and diathermy. I first began to use sodium iodide in this manner about eighteen months ago, and the results that I obtained in my first few cases were so encouraging that I continued its use and have thus far treated seventy-four cases.

The plan that I used in the management of these cases is as follows:

An intravenous injection of a sterile solution of sodium iodide was given every forty-eight hours. The amount of the solution used was twenty c.c., which represented thirty-one grains of sodium iodide (U. S. P.). The solution has been put on the market in ampoules by several drug firms. Thirty-one grains of sodium iodide is an adequate dose where no idiosyncrasy to iodides exists. The solution was not warmed but was at ordinary room temperature when injected. All patients were recumbent while receiving the injection. The injection was administered by means of a sterile twenty c.c. Luer syringe under strict aseptic conditions. The solution was injected very slowly; the injection time covered a period of from three to four minutes. The average number of injections given were four, although in some cases more were given. No local applications were made to the scrotum. Each patient was instructed to support the scrotum with a jock strap, to avoid exercise, to drink about two quarts of water a day, to see that his bowels moved freely each day, and to take a tablet containing five grains each of hexamethylenamine and acid sodium phosphate, four times a day.

There was a decrease in the intensity of the pain in all cases twenty-four hours after the first injection. The relief was much more marked after the second injection, and after the third, seventy-three patients were relieved of their pain entirely. One patient who had a concomitant bronchitis received seven injections before his pain was completely relieved.

The tenderness was less in all cases after the first injection, and was still less marked after the second, while after the third it had entirely disappeared in thirty-seven instances. In twenty-five instances after the fourth, in nine after the fifth, in one after the sixth, and in one after the eighth injection, respectively, the tenderness in the epididymis disappeared, while in one instance slight tenderness persisted for a period of two months even after eight injections.

The effect of the treatment on the swelling of the epididymis was extremely favorable. In practically all of the cases it was slightly less after the second injection, and after the third injection the epididymis was about normal on palpation in eighteen cases. Thirty-two cases required four injections, eight cases five injections, and one case six injections for all easily discernible swelling to disappear. In fifteen cases there remained a small but varying amount of swelling after the injections, which were four in number, were discontinued. In these cases I did not feel that a small, painless swelling, without tenderness, was a sufficient indication to continue the injection treatment. Two cases showed marked swelling in the epididymis and in addition a secondary inflammatory hydrocele, after eight injections. The hydrocele in each instance was emptied by means of a Luer syringe.

The induration in the epididymis became less after each injection. There was noticeable softening after the first injection and the induration was found to be less to about the same degree and in about the same proportion of cases after the third, fourth, fifth, sixth and eighth injections, respectively, as was noted in regard to the swelling. The indurated area did not always get progressively softer after each injection; in some instances it fluctuated, but on the whole it showed a satisfactory improvement.

The number of injections required varied according to the severity of the case. I did not use less than four injections in any case, although at times it seemed as though three would suffice. No case received more than eight injections. The maximum amount of improvement occurred in practically all cases after three injections. In all cases the first four injections were given at forty-eight hour intervals, and if more injections were considered necessary an interval of three days was allowed.

Reactions were absent in sixty-seven cases. Seven patients complained of symptoms, which I considered to be evidence of iodism. Five persons experienced a sensation of tightness about their throats, in the region of the salivary glands; the sensation was noticed within an hour after the injection and lasted for from two to four hours. Two patients developed an intense headache, which came on several hours after the injection and lasted in each instance for about twelve hours. One of the two patients just mentioned also complained of an aching of his arms, legs and back, which lasted for several hours. Dizziness and extreme weakness, in addition to the sensation of tightness about the throat, was noted by two patients; in one instance it came on within a few minutes after the injection and passed off after a few moments, but in the second instance it lasted for several hours and caused the patient to remain in bed for an entire day. The injections did not in a single instance give rise to any chills or fever. No evidence of renal irritation, as shown by urine examination, was found in any case. The pulse rate was counted before and after each injection, and it remained apparently unaffected. The blood pressure was taken before and after the injection in ten instances and it was found to be the same.

All but five of the patients in this series received their injections in my office. Four of the five patients treated elsewhere were in bed when I first saw them, and so I gave them their injections at home, for a period of one week, after which they came to my office. One patient received his first injection at the office, but he became so very weak that I gave him his other injection at his home. He had in addition, however, an acute bronchitis. This same patient when first seen presented an involvement of the left epididymis, and within twenty-four hours the right epididymis became affected. The lack of immediate improvement in this case I felt was due to lowered resistance caused in a large measure by the rather severe concomitant bronchitis. It would seem, therefore, that sodium iodide can with reasonable safety be administered in a physician's office.

Leakage of some of the sodium iodide solution into the tissues during the process of injection, although not desired, is not to be feared, as the patient complains of a slight smarting pain, which dies away in a few minutes. The escape of some of the solution into the tissues occurred during two injections, but I observed no redness or edema as a consequence. Stern and Ritter purposely injected a full dose of twenty c. c. directly into the tissues of one of their patients and they state that "he complained of pain for about an hour, but there was no redness, edema or sloughing."

This method of treatment of gonorrheal epididymitis does not prevent recurrences of the epididymitis at some later period. In this series of cases recurrences occurred in three instances. In one instance the recurrence developed three months after the previous attack, in on instance after five months, and in one instance after seven months. The three patients mentioned above were treated during their first attack with injections of sodium iodide, and the injections were not discontinued until the process in the epididymis had entirely subsided, and I advised them to continue treatment until the infection in the posterior urethra, prostate and seminal vesicles had been eradicated, but all three stopped treatment when I stopped the sodium iodide injections. Therefore, in all cases after the process in the epididymis has subsided, it is necessary to carry out the routine treatment of the gonococcal infection in the seminal vesicles, prostate and posterior urethra. If a recurrence does occur in a case that has been previously treated with sodium iodide, the recurrent epididymitis responds to the injection of sodium iodide a second time as favorably as those cases receiving it for the first time.

Since I began using sodium iodide in gonorrheal epididymitis, I have not seen a single case in which epididymotomy was necessary, and I am convinced that its general use will reduce the number of cases now considered operable to a much smaller minimum than now obtains. In fact, I feel that its general use would seem at least to offer some promise of doing away with the necessity for surgical intervention in these cases entirely. In general, the results that I have obtained by the use of sodium iodide have been far superior in every way to the results that I have obtained by the use of all other methods, singly or collectively.

The mode of action of sodium iodide solutions in gonococcal disease of the epididymis is obscure. Favorable results have been reported from its use in gonorrheal arthritis and prostatitis, but after using it in four cases of gonorrheal arthritis, in four cases of gonorrheal salpingitis, and in ten cases of gonorrheal prostatitis, I discontinued its use, as the results that I obtained in these cases were on the whole discouraging. In this connection I might add that the administration of sodium iodide for gonorrheal epididymitis, did not, so far as I could judge, materially help in the eradication of the disease from the prostate, seminal vesicles, or posterior urethra.

I have observed, however, that intravenous injections of sodium iodide apparently exert a beneficial influence in certain cases of importance occurring in persons having a gonorrheal infection in their prostate and seminal vesicles. My attention was first drawn to this action by a patient, whom I had treated five months previously for gonorrheal epididymitis with sodium iodide, and who had returned with a recurrent epididymitis. When I informed him that I was going to give him some more injections of sodium iodide, he replied that he was glad as the injections administered five months previously had markedly increased his sexual vigor. After this I carefully questioned all of my epididymitis patients about their sexual vigor, and four patients out of twenty-six questioned, gave a history of partial impotence—premature or quick ejaculations, or feeble erections of the penis. These four patients eight months later reported a marked improvement in their sexual powers following the sodium iodide injections, which were given for their epididymitis. Six cases of apparently total impotence, occurring in persons who had also a gonorrheal prostatitis, were treated with injections of sodium iodide. Each patient received six injections. At the end of two months, three patients stated that their sexual powers were again apparently normal, one reported a slight improvement, while two noted no improvement whatever. This indicates, I think, that sodium iodide may become an aid in the treatment of certain cases of impotence in patients in whom gonorrhea is an etiological factor.

CONCLUSIONS.

1. Intravenous injections of sodium iodide solutions are of distinct value in the treatment of gonorrheal epididymitis.

2. Indications are that it might become an aid in the treatment of certain cases of impotence, in which gonorrheal infection enters into the etiology.

3. Its exact mode of action is unknown, but its administration is practically free from danger.

Chronic Gonorrhea of the Prostate and Seminal Vesicles*

By W. H. MORTON, M.D.,
New York.

Gonorrhea is chronic when it has lasted for over six weeks. It is dependent upon pathological changes which must be understood in order to apply the proper treatment. In most cases, especially those of long standing, both prostate and vesicles as well as the urethral canal participate in the pathological changes and a systematic examination is necessary to locate the various lesions.

The important pathological change in the tissues in chronic gonorrhea is the infiltration of small round cells under the mucous membrane surrounding and embedding Morgagni crypts and Littré's glands, their mouths being held open in some cases, in others tightly closed, their cavities incubating colonies of gonococci. If this infiltration is superficial it is absorbed; if extensive, it is converted into connective tissue, forming strictures and erosions with granulations and a gleety discharge with exacerbations.

The treatment is designed: 1. To rid the tissues of gonococci; 2, to cure catarrhal inflammation and promote formation of epithelium over the erosions; 3, cause absorption of infiltration; 4, restore intraglandular and periglandular infiltration and inflammation.

These indications can be met by irrigation of the urethra with antiseptic and astringent solutions and by dilatations with sounds and dilators. The solutions used are silver nitrate every second day, or potassium permanganate every second day, as soon as the diffuse inflammation is reduced to isolated spots, as denoted by the first glass being clear with shreds which persist until cured.

Absorption is promoted by passing steel sounds to 30 or 32, doing mestatomy if necessary. Gentle massage over the urethra, over sounds, with the fingers helps. In recent cases sounds are passed every fourth day; if the reaction has subsided in hard infiltration the interval should be one week. This is of course contraindicated in recent inflammation. One should wait until the urine contains only shreds. Large numbers of cases require larger dilatations than 32 French to reach deep seated infiltration, which indications can be met with Kollmann's dilator, gradually increasing the size to avoid tearing the mucosa.

Many intractable cases of gonorrhea, lasting for years in spite of treatment, are caused by chronic inflammation of Morgagni's crypts. They show few symptoms, usually only the morning drop, but are characterized by acute exacerbations after slight provocation, leading the patient to believe he has a fresh infection. Urethroscopic examination shows a few open and inflamed mouthed crypts; in others the mouths are occluded by the growths of epithelium. When these crypts are infected the gonococcus may remain in them for years, the patient remaining a carrier of infection. These cases should be treated by dilatations at the beginning with a full sized sound, followed by irrigation, but later a Kollmann's dilator should be used once a week, increasing one or two numbers at a time. Usually a maximum dilatation of from 40 to 45 will suffice to open the glands, force out the purulent secretions, and cause absorption of periglandular infiltration and a return to normal. Not uncommonly, however, this will not suffice; a few crypts persist to harbor the infection and inflammation. These should be destroyed with the cautery, three or four at a time, through an endoscope. The cauterization must be rapid and superficial to avoid stricture formation.

The posterior urethra is involved in from forty to eighty per cent. of all cases of acute gonorrhea. Many cases never become chronic, but when they do the posterior urethra remains inflamed as often as does the anterior urethra. Acute posterior urethritis is invariably caused by gonorrhea, but the chronic form is caused in other ways, especially by excessive coitus or sexual abuse, such as masturbation and withdrawal. In the presence of free pus, urethrovesical irrigation with silver nitrate solution, one to one thousand, or potassium permanganate, one to three thousand, rapidly reduces the purulent discharge. After the urine is clear, examine the vesicles and prostate and massage if diseased. When urethral examination shows inflammation localized to the colliculus, direct application of nitrate of silver solution, fifty to one hundred grains to the ounce, once a week through the posterior urethroscope will be required. Granulations in posterior urethra should be cauterized with strong solutions of silver nitrate, and small polypi or granulations of colliculus may be removed with silver scissors or the galvanocaustic paint. If the utricle is infected, inject with solution of nitrate of silver. The hard submucous infiltration is absorbed after dilatation.

Acute Gonorrhea*

By W. F. McKENNA, M.D.,
Brooklyn, N. Y.

The acute phase of gonorrheal infection offers to the urologist an opportunity to exert an immense influence for the ultimate good of his patient. The successful management of the inflammatory process in the early stages may be the means of saving a long and tedious course of treatment, and avoiding the disheartening sequelæ which so frequently occur in many of the indifferently cared for cases.

Acute infectious processes anywhere must be considered from a different angle than those which have become chronic in their character. Particularly is this true of acute gonococcic infection whether it be in the genitalia or elsewhere. The dividing line between acute and chronic gonorrhea rests to a great extent with the individual surgeon, and depends largely upon his personal experience. It may be well to define the limits of acute gonorrhea as "any recent and active inflammatory process in the urogenital system, caused by the gonococcus."

In my own practice it is my habit to make a more or less definite division of the cases into three groups, depending upon the region involved and the extent of the lesions present.

Group 1, comprises all those cases which are still limited to the anterior urethra; group 2, consists of a small number of cases in the early posterior stage where no adnexa are affected; group 3, embraces all those cases in which posterior urethritis is present, complicated by infection of one or more of the adnexa. This classification of cases while arbitrary to some extent gives a standard for diagnosis, and in no way prevents further and more accurate grouping for special purposes.

In group 1 are found all those cases in the initial stages, and some of the more fortunate later ones where the second glass of urine is still clear, and none of the organs beyond the compressor muscle are affected. In group 2 are those few cases in which both glasses of urine are turbid, where no spreading of the process has occurred into the deeper structures, and none of the symptoms of posterior urethritis are present. This group of cases may still be thought of as simple urethritis behind the compressor, but still on the mucous membrane, without having penetrated into the submucosa, and not involving the adjoining organs.

In the third group appear those cases which are characterized by the frequent, burning, urgent urinary efforts which are sometimes accompanied by terminal hematuria. It is here that some degree of adnexal infection is always present, and this is the group of cases that must be watched with the greatest concern by the conscientious urologist. Even after the apparent subsidence of the severely acute period these are the cases that often harbor infection for long intervals without proper surveillance. It is this type of case that continues to have reinfection after reinfection, and that carries the gonococcus into new and fertile fields.

For the purpose of laying down principles of treatment groups 1 and 2 may be considered together as being both surface infections, though they differ vastly in their possibilities of early cure. In the purely anterior cases the failure to get a good result with reasonable care and attention is rare. In the deep superficial, or posterior superficial cases the odds are that the infection will spread. In the cases that have already reached the prostatic ducts, the ejaculatory ducts, the prostate gland itself, the vesicles, or the epididymes, the methods and indications are entirely different.

The pathology underlying these several lesions must be fully appreciated before any line of treatment can justifiably be undertaken. Gonorrhea has a pathological anatomy just as any other disease, and this fact is often overlooked by many practitioners. There has been and still is so much of empiricism and mystery about gonorrhea in many minds that it is time a rational and intelligent basis was found for any therapeutic measure which we intend to employ. The first consideration is the anatomy involved, and its accessibility to treatment; the second the physiological reaction of its region to the agents employed; the third the technical details of applying the remedies selected.

In the first group of our cases the object is to limit the infection to the area already affected. In the anterior group of cases this is a comparatively simple problem. The pendulous urethra is easily accessible, and offers no obstacle to direct medication. The indication here is sterilization of the mucosa. Until the introduction of the acridine series of dyes this sterilization was attempted by such antiseptics as potassium permanganate, argyrol, protargol, albargine, and a host of other lesser remedies, with somewhat disappointing results. Since acriflavine has been available I think that it is possible in most of the group 1 cases to keep the infection within bounds. Either as an irrigation, or as a hand injection to be used by the patient, or better, a combination of the two, properly prepared solutions of acriflavine will almost always sterilize the mucosa of the gonococcus, and do less damage than any other single preparation. Its one disadvantage is that its use cannot be prolonged beyond a period of two weeks without causing some submucosal infiltrations. The strength employed is one to four thousand or less in distilled water or normal saline. In this dilution the solution is usually nonirritating, even when used three or four times a day. Most satisfactory results have been obtained when four to six ounces are allowed to run into the bladder, after washing the anterior urethra with an ounce or two. This is held in by the patient who grasps the meatus snugly, with the urethra gently distended, for a period of five minutes by the watch, when it is voided. Another quantity of about three ounces is then introduced and the patient retains this until he voids again. If irrigations are employed, they should be given once or at most twice daily, and the hand injection be used twice. If no irrigation is used, the hand injections should be taken three times a day. I have seen so few mishaps with this procedure in my own hands that I use it as routine whenever possible. The results are so uniformly good that only those variations suggested by experience in the hands of the user himself should be attempted.

---

*Read before the Section in Genitourinary Surgery, New York Academy of Medicine, March 21, 1923.

Diet is an important factor in the care of acute gonorrhea, although the restrictions laid down by some authors are ridiculous. A bland, moderately nourishing food intake with meat limited, condiments and spiced foods excluded, with plenty of cereal and fruit units will in no way harmfully affect the patient. Liquor of any kind is forbidden, not altogether because alcohol is detrimental, but because it induces overexcitement and indiscretions. Muscular activity should be limited to the minimum for the status of the patient, and complete rest would be ideal if it were practicable.

In the acute phases much has been written about the use of vaccines, but in my experience they are totally useless in the group 1 and 2 cases. There is so little specificity in the gonococcus protein as it is ordinarily provided that in anterior and in superficial posterior cases the use of specific vaccines is hardly warranted.

The use of the various urinary antiseptics is very questionable therapeutics. There is no proof that hexamethylenetetramine, were it as much of an antiseptic as is asserted for it, ever reaches below the topmost layer of the epithelial lining of the passages. It is without any cleansing effect in the dilution in which it comes through the urethra. The same objections apply to the several balsams whose use is almost wholly superstition handed down from former generations.

Water is probably one of our best medicines in any stage of gonorrhea, just as it is of value in any inflammatory process. In urethritis its free use will give a bland nonirritating urine to flush the parts frequently, and will serve to reduce the toxic effects especially seen in the posterior cases.

The use of heat locally in the form of hot baths, or as an external application, is sometimes very grateful, and often serves to quiet the discomfort in urination if present. Cold may be substituted if more agreeable to the patient. If there are painful erections some simple sedative may be prescribed, and if this fails, camphor in oil may be injected into the gluteal muscles. In anterior cases it is rare to have to resort to narcotics. A suspensory should be worn by all patients even from the very beginning.

In all manipulations whether by the surgeon or the patient the utmost care and gentleness should be insisted upon, in order to avoid damage to the mucosa as far as possible. If the treatment outlined above is successful, and it is in ninety-five per cent. of the anterior cases, and in about thirty per cent. of the superficial posterior cases, the result is the disappearance of all gonococci in from seven to fifteen days. There will still be seen a thin watery discharge which shows leucocytes and epithelial cells, but there will seldom be found any gonococci. This thin discharge will remain watery in character or disappear if the infection be ended. If the mucosa has not been sterilized, the discharge quickly assumes the same appearance as in the acute cases. Those cases remaining free from discharge for forty-eight hours after the cessation of all treatment, may be considered cured tentatively, although the cure cannot be as yet scientifically established. These cases may be allowed to rest from further treatment for a period of two weeks, although the hygienic regimen should be maintained as before.

At the end of two weeks, the presence of infiltrations along the mucosa is estimated by the use of the *bougie á boule,* and the appropriate sounds are passed at weekly intervals until the natural calibre of the urethra is restored. The first examination is made upon a bladder full of acriflavine, so that if by any chance there are gonococci present in the glands they will be killed before fresh harm can be done. I rarely make the silver nitrate provocative test until the end of the fourth or fifth week.

If acriflavine does not produce the effect of completely sterilizing the mucosa its use should be discontinued as its continuance will inevitably cause dense stricture formation. It will be wise to shift to some other solution such as permanganate, or protargol, and await the disappearance of the discharge, when the same procedure as before should be followed before the patient can be discharged.

Unfortunately we are not universally successful in this as in any other disease, and occasionally an anterior case does not clear up and the posterior complications develop. This occurs more readily in the cases which we see for the first time in the posterior superficial state. It is often said that the infection is "driven back" by the use of injections and irrigations. This appears to me a fallacy, as it is extremely unlikely that the infection travels along the surface of the urethra, but is rather transmitted by the lymphatics, in the submucosa. I have seen as many cases of posterior infection in cases that have never had any injections or irrigations, as I have in those where these measures have been employed.

Those cases in which the adnexa are infected present an entirely different picture from that seen in groups 1 or 2. While the anterior urethra has a naturally good drainage, if there be no deformity, there is no external drainage in the deep urethra. Such drainage as is present is backward into the bladder, due to the fact that the internal sphincter relaxes more readily than the compressor muscle. It is this fact that accounts for the second glass of urine being cloudy in the posterior cases. In these cases we are no longer dealing with surface infection, but with actual invasion of the deep structures. From a philosophical viewpoint we may consider these cases in one group regardless of the special organs involved, although each has its own special indications. The organs are usually infected in about the following order, based on the frequency of occurrence; prostate, vesicles, epididymis. The vesicles are apt to give fewer signs of infection than either of the other organs, although they are invariably infected if the epididymes are.

It makes little difference which of these organs is affected, so far as the general principles of treatment are concerned. The most important single measure is rest, as complete as can be obtained for the patient. All muscular exertion should be avoided, particularly heavy lifting, and excitement of any kind is deleterious. Next in order is heat, locally applied, or cold if better born. For the prostate and vesicles this takes the form of the rectal douche or the sitz bath; for the epididymis, the hot water bottle or the ice bag. A very effective method of getting heat into the deeper structures is the high frequency bipolar current. This is used for the prostate and vesicles with one pole in the rectum, and one over the lower abdomen, or in the perineum; for the testicle one pole above and one below is effective. If this can be tolerated it gives great relief and seems to shorten the duration of the infection.

Sometimes the suffering is severe, though seldom unbearable, and it would seem that operative relief were imperative. Particularly is this true in epididymitis. I have never opened, or assisted at the opening of a prostatic abscess, or of an epididymis for gonococcic infection. The majority of the cases will go on to spontaneous absorption, without interference, and the sequelæ are easier to handle.

Local treatment by injection or irrigation must here be avoided, first because of the danger of doing direct damage to the parts, and second because the remedies employed cannot reach the areas mainly affected. Again, attempts to sterilize the urine have no effect on the general course of the disease and the urinary antiseptics and balsams are mentioned only to be condemned. There is absolutely nothing to show that these substances are present other than in the urine, and they do not penetrate the tissues at all, nor come in contact with the organisms below the surface. No case will ever be cured by their use alone, if no other measures are taken, and most patients do better without them than with.

Inasmuch as all these patients with posterior involvement display some degree of general bodily reaction, I am convinced that any agent which will serve to raise tissue immunity either specifically or nonspecifically is of value. The various gonococcus vaccines that I have used have been a disappointment, whether simple or mixed. They have little or no local reaction, and they generally do not produce any general reaction. We do know that persons develop some degree of immunity as evidenced by the fixation tests, although the immunity is of low strength, and of short duration. Whatever the immunity mechanism may be it is not stimulated by the gonococcus vaccine in most persons. I believe, and my experience seems to bear me out, that the resistance processes are best stimulated by the use of some nonspecific protein which gives a high degree of local and general reaction. The Bacillus typhosus vaccine commonly used for immunization gives the best results both in local reaction at the point of injection, and in general febrile reaction. It is during this reaction to the nonspecific protein that the immunity system is stimulated into activity, by the gonococcus antigen already present in the course of the disease. I use an initial dose of a half mil. and repeat on the third or fourth day. It is rarely necessary to give more than three doses before the infection is well on its way to resolution.

For the urgency and frequency the use of alkalies is very good, and liquor potassæ in from five to eight minim doses is effective; citrate of potash is valuable, as is bicarbonate of soda. Fruit juices are well tolerated and serve the same purpose. Among the sedative drugs the tincture of hyoscyamus is excellent in thirty to sixty minim doses, although pharmacists will continue to object to the size of the dose. In some few cases the suffering may be so severe that only one of the opiate drugs will give relief.

It is hardly likely that every case will come to such extreme difficulties as are herein outlined in the acute stage, although gonorrhea may sometimes be a severe and distressing disease. It will be possible to make bearable such complications as do occur if some of these suggestions are followed. It will also hasten the ultimate cure if care is taken in the early stages.

When Is a Man Cured Who Has Had Gonorrhea?

By WALTER M. BRUNET, M. D.,
Brooklyn.

The practice of medicine is a commercial enterprise or a profession according as the motive of financial gain or human service takes precedence. The physician is frequently called upon to render services which can never be repaid with coin of the realm. Of such a nature is the counsel he is sometimes asked to give when a young man who has been infected with gonorrhea wishes to know when it will be safe for him to marry. Because he is conscientious he wants a specific reply. He wishes to be assured beyond a peradventure that there is absolutely no possibility of transmitting his infection to the girl whom he expects to marry. Vague generalities based on collected statistics on the prognosis of gonorrhea, useful as they may be to the doctor, cannot satisfy this inquirer. It is well enough for the physician to know that in the large majority of cases which receive proper treatment, the danger of infecting the marital partner is slight, but the patient wishes to know, and has a right to ask, whether in his particular case the infection is entirely banished. The advice given him may determine whether the future of the questioner and of the woman who has agreed to tread life's path with him shall be a joyous one or a black tragedy. And whether he likes it or not, the physician confronted with this vexing medicosocial problem is expected to shoulder his share of the obligation—his share we emphasize, for it would be obviously unfair to burden him with full responsibility since medicine has not yet been reduced to an exact science, and no doctor can predict with certainty or guarantee the outcome of any given pathological condition. What may fairly be expected of the doctor is that he familiarize himself with all methods and procedures designed to determine when gonorrhea is cured and, further, that he be able to give his patient a clear, intelligible reply. If in a given case it is impossible to give a categorical answer, the physician must at least be able to explain the situation to his patient so that he, in turn, may assume the full responsibility of his undertaking.

An examination of the literature bearing on the determination of cure of gonorrhea reveals that opinion is not unanimous and that standards proposed by various authors are by no means fully accepted by others. Some, being of the conviction that no test for the determination of a cure for gonorrhea can be too drastic, insist on very rigid standards. Others advocate a mild type of test and are satisfied merely to know that in the struggle of bodily resistance versus the infecting organism the former has at last gained the upper hand. This may satisfy the superficial and may be sufficient in so far as the physical wellbeing of the patient is concerned, but it does not take into consideration the important fact that gonococci which have become attenuated or held in check by a newly acquired resistance, may, when transplanted on virgin mucous membrane, set up a new infection more disastrous than that of the original infection. Mild standards, therefore, cannot be too severely condemned. On the other hand, too severe tests tend to prolong treatment to the point where it does actual harm and also to make of the patient an introspective neurasthenic. Somewhere between the two extremes lies the sensible course—a workable standard which the conscientious practitioner may apply in the knowledge that his full obligation has been discharged and that the welfare, physical and mental, of the patient is safeguarded. Perhaps a brief survey of the several tests which have been proposed by various investigators would be timely.

The alcohol test.—The irritating effect of alcohol on a urethral infection has been so well established that it was utilized as a test for the cure of gonorrhea. If, after extended treatment and cessation of the gross symptoms, the patient imbibed freely of beer or other alcohol and there followed no relapse, the patient was declared cured. This method of determination of cure is, to say the least, unscientific and inexact.

The fatigue test.—Hard work or exercise carried on to the point of fatigue is likely to light up a dormant gonorrheal infection, if such exists. If, after such fatiguing exercise, the discharge does not appear and the urine remains clear and shredless, the presumption of a cure is favorable. But only as the test is negative can it be relied upon with any assurance.

The discharge test.—A urethral discharge may exist even after all gonococci have been eradicated. Such discharge is probably due to overtreatment from the irritation following medication or instrumentation. But so long as a discharge of any kind exists the patient cannot safely be declared cured. Stickiness of the meatus implies that a slight discharge is present. Gentle massage of the urethra from bulb to glans generally brings to light a discharge if present, but Fraser (1) warns insistently against this procedure.

The urine test.—It is best to apply the two glass test to the first urine passed in the morning. A clear urine alone means little, though it furnishes presumptive evidence that there is no active inflammation. On the other hand, shreds may persist indefinitely and do not necessarily prove the presence of urethritis. Shreds may at times be found repeatedly in a normal individual. It is necessary also to inspect the urine passed immediately after prostatic and vesicular massage.

The vaccine test.—After all symptoms have subsided a dose of gonococcus vaccine (100,000,000) may provoke symptoms if there are hidden or latent lesions. The vaccine test is not to be resorted to until several symptomless days have passed. This test has definite value and is harmless, but must be interpreted only in conjunction with other tests.

The cultural test.—Herrold (2) has concluded that cultures made of expressed prostatic and seminal fluids on phosphate agar with blood and ascitic fluid on plates incubated under reduced oxygen tension, are the most reliable single means of determining the termination of a gonorrheal infection. He has demonstrated that the test is positive in many cases in which all other tests have been negative. To carry out the test requires, of course, special laboratory equipment and training.

The complement fixation test.—The reaction of this test depends on the presence of specific antibodies in the blood and the results, as is the case with the Wassermann test, require a careful interpretation. If there be a colony of gonococci walled off securely from the general blood stream, the test may be negative and the superficial observer may be led astray. In fact, there are a number of variable factors involved in the test, hence the possibilities of error are many and the reliability of the test is questionable.

The microscopic test.—As a diagnostic measure the demonstration of the gonococcus by the microscope is perhaps the surest proof of gonorrhea. Systematic microscopic examinations are serviceable during the course of treatment as the relative number of gonococci and the changing picture of cellular content of the smear furnish a valuable gauge as to the course of the disease. However, as a measure of determining the cure of the infection, microscopic examinations are of little value. At best, it is difficult to demonstrate the gonococcus in a patient who is almost well. As previously noted, so long as there is any secretion the patient cannot be declared to be noninfectious.

Some investigators have argued that the gonococcus gradually loses its virulence and that the patient, to all intents and purposes, may be cured and yet harbor the germ in his urogenital tract. This may be true but it is yet to be proved whether the abatement of symptoms is due to a real loss of virulence of the gonococcus or to the development of a resistance on the part of the host sufficient to hold the gonococcus at bay. If the latter is true, it would be most unwise and pernicious to discharge as cured a patient who is symptomless but who still has gonococci present in his tissues, for if these germs are transplanted on new or virgin soil they are likely, even assuming that their virulence has been attenuated, to take a new lease on life, so to speak, and set up a violent inflammation. It requires no great strain on the imagination to picture the possible results of such a happening. As long, then, as gonococci may be demonstrated, it is unsafe to declare the patient cured no matter if all other symptoms have disappeared. In examining smears made of prostatic and seminal secretions due attention should be paid to the cellular count. Leucocytes and pus cells mean inflammation, and so long as they are present cure is out of the question.

The urethroscopic test.—It would seem that if all other tests had proved negative urethroscopic examinations would be superfluous. If after several weeks all symptoms have abated, a urethroscopic examination which reveals a normal mucosa throughout the tract is reassuring. If practicable, such an examination should be made.

These are the tests generally advocated for the determination of cure of gonorrhea in the male. After this brief consideration of them what conclusions may we draw? The most obvious is that no single measure can be relied upon to determine a cure, but that several, sometimes all, must be performed and the results carefully correlated and interpreted in order to decide the question. Determination of cure is but the art of making an exact diagnosis. Osler,Cabot and others of our great teachers have emphasized the point that a diagnosis is seldom based on a single finding or symptom. It is only by painstakingly gathering all available objective and subjective evidence, weighing it and carefully considering it from several angles, that a scientific diagnosis can be made. The determination of a cure in gonorrhea cannot be reduced to a simple, exact formula. There is no slide rule with which to calculate the answer. The personal equation enters in and the possibilities of faulty judgment are always present, but given a reasonable chance and a cooperative patient, the average, welltrained general practitioner, assuming that he has a conscience, may safely be relied upon to find the correct answer to the important question.

Another conclusion to be drawn is that the time element is extremely important. It is a mistake to lead the patient to expect a speedy cure, for with each disappointment his discouragement is likely to increase. No attempt should be made to determine a cure until all symptoms have ceased for at least three weeks. Nor should the doctor be too hasty in declaring the patient cured. Subsequent examinations, two, three, and six months later, should be made, especially if the question of marriage hinges on the issue.

A third inference to be drawn is that mere laboratory tests are not sufficient. Good physicians of the old school lacked many of the refinements of diagnostic technic which we enjoy today, yet performed creditable work because they observed and scrutinized the general condition of the patient and followed the stages of his condition carefully. General clinical observation, including examination of the urethra for stricture, possible abnormalities of the epididymis, and, if possible, a urethroscopic inspection, should be made to confirm the findings of the special tests. By no means unimportant is the consideration of the patient's mental condition. Many a man has suffered more psychic than physical trauma, as a result of a venereal infection.

This is hardly the occasion to warn against the danger of overtreatment but it should be kept in mind that an overzealous physician in his determination to establish a cure tends to employ too drastic methods or to prolong treatment, much to the detriment of the eventual welfare of the patient. The urogenital tract may not with impunity be abused by extensive instrumentation or medication. In many instances it is well to suspend all treatment for a limited period of time.

It is significant that the determination of a cure in gonorrhea was one of the important questions which engaged the attention and deep study of the All America Conference on Venereal Diseases, held in Washington, December 6 to 11, 1920. To Sections 3 and 4 of this conference were assigned special questions bearing on the scientific aspects of gonorrhea in the male and female. The sections were composed of recognized leaders in their fields in this and other countries. One of the efforts of these sections was to determine, if possible, criteria for pronouncing a case of gonorrhea cured, which would be safe in the hands of general practitioners and at the same time practicable. The results of the long, careful deliberations of the sections took form in a resolution which was adopted later by the General Conference Committee. The text of the resolution is as follows (3):

"*Resolved,* That with our present knowledge it is not scientifically and medically practicable to establish a standard for determining when gonorrhea is cured. This statement, however, must not be understood as reflecting upon the ability of any specialist to make such a decision."

The next paragraph of the resolution discusses the reasons why it is difficult to establish a standard of cure in the female. The resolution continues:

"On the other hand, in the male it is practicable to establish a reasonable standard for determining when gonorrhea has been 'probably cured.' The criteria are based upon two distinct entities—a, cure of the infection; b, cure of the lesions of the disease.

"In gonorrhea, whether in the male or female, the duration of infectiousness has but a single slight relation to duration of the lesions—that is, the symptoms may continue long after the infectiousness has ceased, and, conversely, infectiousness may persist after all obvious symptoms have ceased.

"As the problem is confined exclusively to the question of infectiousness, the word 'cure,' as here used, will be understood as equivalent to cessation of infectiousness.

"There is no combination of clinical facts which constitutes conclusive evidence of a cure of gonorrhea in the male. Therefore, the determination as to whether cure has been effected depends upon the acumen and skill of the physician. The patient may be assured that he is probably cured if all of the following criteria are fulfilled:

"a. No urethral discharge whatever for one month, during which time the patient is under observation without treatment.

"b. The first ounce of urine passed in the morning free from any cloud of pus, as examined in a glass or bottle by a strong light.

"c. All shreds in the urine continue to float at least two minutes after agitation of the fluid has ceased.

"d. Massage of the prostate and seminal vesicles expresses a fluid which, when examined under the microscope, is found to contain no gonococci or pus cells.

"e. It should be possible to pass a 26 F sound into the bladder, and examination the following day should satisfy conditions a and b.

"f. If these findings are confirmed at a second examination one month later, during which time there have been no symptoms or treatment, the patient should be regarded as cured.

"All other cases should be examined by an expert, in order to determine whether or not they are cured."

Naturally, this body of recognized authorities drafted their resolutions with exceeding caution. What they are chiefly concerned with was the question of limiting the spread of gonorrhea, hence without quibbling over the academic meaning of the word cure, the criteria were drawn up to apply to the determination of the cessation of infectiousness. On first glance it is somewhat discouraging to note that the sections dared not commit themselves beyond establishing a reasonable standard for determining when gonorrhea is probably cured. On the other hand, the standards advocated are obviously simple, fair, and include as much as may be reasonably expected from the general practitioner. May we repeat that the determination of a cure in gonorrhea depends more on the acumen and judgment of the physician than it does on certain set rules or rigid procedures?

Neisserian Infection Treated by a New Modality, Infrared Light

By W. D. CHESNEY, M.D.,
Chicago.

Dorland defines light as "ethereal vibration which gives origin to the visual sense." Webster's definition is still more obscure but from these definitions has arisen great misconceptions of the truth of light and its application to medicine. Maxwell's theory is undoubtedly the right one: "Light is electromagnetic vibrations." This is true regardless of whether it has to travel through ether (Lodge, *et al*) or whether there is no such thing as ether (Steinmetz).

Light, as defined by Dorland and Webster, shows a peculiar analogy of a general acceptance of the truth of the theory as an exception to the truth, for the light affecting the visual sense consists of only seven colors, each characterized by a certain and unchangeable wave length. Change the wave length and you change the color. Light, then, affecting the visual sense, consists of seven eighths of an octave. While, at the same time, it is known that of light visible and invisible there are sixty-seven octaves or approximately seventy-five times as much light which does not impress the optic nerve as that which affects the visual sense.

The average physician, seeing the operation of the Crookes tube, for the production of x rays, or the mercury arc in quartz for the production of ultraviolet rays, is likely to forget that these rays are invisible. Both of these devices produce more or less visible light of peculiar colors, which are mistaken for the desired rays.

The spectrum of the quartz mercury arc shows as follows: Visible to the human eye, twenty-one per cent.; infrared (invisible to the eye), fifty per cent.; ultraviolet (invisible to the eye), twenty-nine per cent.

The ultraviolet band of the spectrum covers less than two octaves and is situated immediately above the visible spectrum. Immediately below the visible end of the spectrum is situated the infrared spectrum, which covers about nine octaves. That is about four times the ultraviolet spectrum, and ten times the visible spectrum.

As opposed to the ultraviolet spectrum the infrared shows slight actinic or chemical properties. It is constructive, as upon it depends all vegetation, hence our life depends upon infrared (1). But its greatest usefulness depends on its ability to penetrate substances deeply, and in this way exercise a healing warmth.

Have you ever noticed that deep drifts of snow melt more at the bottom than at the top, when the sun shines on it? This is brought about by infrared rays. These rays penetrate deeply before being converted into heat and therein lies their great value in medicine.

Every healing process requires an increased temperature. A bone is broken. Nature sends an additional supply of blood and higher temperature to the area to heal it. To make the matter more precise and exact, Nature requires an active hyperemia for repair and any agent that will cause this active hyperemia is a curative agent of highest value. It is difficult to consider a single pathological condition, in which stasis does not exist, and any agent that will bring an additional amount of freshly oxygenated blood to a diseased area will tend to destroy the infection and hasten resolution.

One of the most important observations made during the World War was this—If a soldier had either an acute or chronic stage of Neisserian infection, and if at the same time he had some condition causing a febrile state in which the temperature was above 99.7°, the Neisserian infection was cured if the increased temperature from the secondary infection persisted for a few days. If this is true, and the fact is attested to by many careful observers, what more rational method of treatment could be devised than one which would give to the affected area a local temperature of 100°.

The theory is that this continual temperature, although only slightly above the normal temperature at which the micrococcus lives, is sufficiently high to lower its resistance until the normal protective processes of the human organism can control and finally destroy the invading microorganism.

Robinson (2) observes "Just as gonorrhea is one of the greatest factors in causing *impotentia cocundi,* so it is the greatest factor in *impotentia generadi."* . . . "Here again we meet with the gonococcus as the greatest factor in race suicide." . . . "Gonorrhea is one of the greatest factors in sex impotence" and most important, as he states: "The danger is not alone in leaving active or dormant gonococci which may in years to come infect and wreck the life of a healthy young wife; there is also danger of leaving a hyperemic patch in the posterior urethra which may come in time to become the direct cause of impotence." Dr. G. W. Overall (3) states: "Seventy per cent. of all blindness and seventy-five per cent. of all diseases of women are traceable to prostatic urethritis following acute gonorrhea in men." White (4) says, "I know that the majority of men who have been infected with gonorrhea have not been cured and are capable of infecting their wives."

A host of authorities assert that the majority of men over forty-five years of age have pathological prostates as the result of gonorrhea, probably acquired in youth and supposedly cured.

And what do we find as the result of prostatic disease—the entire gamut of neuroses and psychoses, chronic invalidism.

But *retournons aux nos moutons,* if we accept the statements so well attested that a continuous temperature of slightly above the normal 98.6°, will lower the virility of the gonococcus to the extent that the normal body protective agents will destroy the invader we are brought to the question of what modality will harmlessly produce this slight increase in local temperature.

Snow (5) makes this unqualified statement: "Radiant light penetrates the tissues to the depth of four to six inches, the infrared rays of the invisible spectrum penetrating to the greatest depth. Radiant energy is converted into heat units in the structures beneath the skin to considerable depths even through layers of bone. Naturally the energy of the effect diminishes with the depth, but the hyperemia resulting from the heat produced in these tissues as well as the effect of light renders remarkable service in point of increasing nutrition, metabolism, and phagocytosis."

Heat as applied locally to the surface by hot water bottles, or electric pads, can be of little service as the heat is carried away by the vascular system as rapidly as it is transmitted to the epidermis. Considerable improvement was made in the use of the urethral and rectal psychophore, but the greatest difficulty was in the fact that there was more or less leakage of water, the impossibility of getting and maintaining the water at the right temperature for the long periods of time necessary so to weaken the virility of the bacteria that they could become prey to the phagocytes and antibodies in the blood stream, and the heat was only obtained at the required point by simple conduction through the tissues. Quite often, too, the heat was disseminated before it reached the focus for which it was intended. Yet with all these drawbacks excellent results have been reported by careful observers.

Thiedering's conclusions regarding the penetrating properties of infrared radiations and their deep hyperemic producing capabilities agree most exactly with those of White, Snow, *et al.* Their conclusion is so important that it will be well to repeat it.

"Infrared rays are not heat but are light rays capable of deep penetration into human tissue and there converted into heat, thus obtaining the healing and safe hyperemia so necessary to repair and relieve from hyperesthesia."

The infrared rays were first used in Germany as a curative agent and some wonderful clinical reports from there attest their value in many untoward conditions. However, the German apparatus was bulky and difficult to handle and the wave lengths produced were not the most desirable lengths for the best therapeutic action, and it again devolved on Yankee ingenuity to devise and perfect a set of infrared appliances.

The orificial appliances are constructed of a material, which, after long and careful tests, most nearly approximated a perfect black body, and when heated to a moderate temperature, produce the greatest amount of invisible infrared light rays.

The well known principle of physics (the total absorption of radiant energy by reflection from the walls of the hollow wedge) is used in a set of appliances for external application. A long series of laboratory tests show that the instruments give off a large volume of infrared light which deeply penetrates human tissue and produces an active hyperemia even in the bone marrow on the heavy bones of the skeleton.

Light therapy has arrived and it is here to stay and it is not long until it will be accepted by every medical men as the one greatest modality in the prevention and treatment of disease. The infrared section of the spectrum of radiation covers many times the wave length values of any other section and in the near future it will be recognized the greatest section as an agent of metabolism correction. And when the matter is sifted to its final analysis, improper metabolism probably stands first as the true etiological factor in disease.

The careful physician will watch with great interest the development of this modality.

The series of infrared appliances for the use of the genitourinary specialist consists of a set of three sizes of infrared rectal dilator irradiators; one infrared prostatic irradiator; one colonic infrared irradiator; three sizes infrared urethral irradiators.

In addition the various sizes and types of external applicators can be used over the various foci, as for instance, over the perineum, the pubes, and the ovarian region.

Unilateral Bifid Ureter, With Duplicate Ureter and Ureterocele on Opposite Side

By FRANK A. ROBERTS, M.D.,
Newark, N. J.

Ureterocele, ureterovesical cyst, or cystic dilatation of the lower end of the ureter was considered a rarity before the days of cystoscopy. Before 1905 only fifty-two cases were reported in medical literature, the greater number having been found postmortem, or during vesical operations. The vesical end of the ureters are dilated into a pendulous pouch filled with urine which remains *statu quo* if of long standing. If of recent formation there is a ballooning effect, which deflates and inflates, inflating with each influx of urine from the kidney and slowly deflating as the urine escapes through a pinhole ureter opening, usually situated on the most prominent part of the cyst. In my case, however, the supernumerary ureter orifice was found on the floor of the tumor after removal and was not of the pinhole variety, but a fairly large aperture. Calculi are sometimes found in these pouches.

These ureteroceles or cysts give a glistening pearl gray appearance, with bloodvessels coursing through the external surface. Cystic dilatations of the lower end of the ureter must be differentiated from ureteral prolapse which it most closely simulates. The two conditions are frequently mistaken for each other. Some textbooks do not differentiate between the two.

Prolapse of the lower end of the ureter is an acquired condition and is usually due to inflammatory causes. There are two kinds of prolapse, one of the mucosa alone (as after passage of stone) and one of its entire ureteral wall. In prolapse the ureteral orifice is not contracted as in ureterocele, but is dilated and the ureteral mucous membrane protrudes through the enlarged orifice. In ureterovesical cyst the delicate bloodvessels can be seen coursing over the surface. Occurring at all ages, in infants as well as in adults, seems to clinch the congenital theory.

Other abnormalities, such as hypospadias, cleft palate, and duplicate ureters, are often associated with ureterocele, and at times are bilateral, as reported by Portner.

These cysts may become so large so as almost to fill the bladder and protrude from the urethra causing intense tenesmus and hematuria.

ORIGIN.

Some cases are inflammatory in origin, these being in the minority, while the majority are undoubtedly congenital. The great majority seem to be due to a stenosed ureteral orifice which, undoubtedly, was congenital. In my case, however, the orifice was quite large.

DIAGNOSIS.

The diagnosis was made by means of the cystoscope. Inspection might reveal a minute punctiform meatus which cannot be catheterized, even with the smallest filiform. The ureteral meatus is situated on the side or summit of the swelling, and is so stenosed as to present a pin point orifice, between contractions the cyst collapses, and if the meatus becomes occluded destruction of the kidney follows. If the cyst is of long standing it may be found distended at all times, independent of contraction. Catheterization of a ureterocele may be difficult or impossible. At times it is followed by a steady stream of urine indicating retardation in a dilated ureter and pelvis.

The symptomatology of ureterocele varies according to the degree of its advancement and length of time of its existence. It may exist for some time without causing symptoms. The symptoms are usually renal, while bladder symptoms are secondary to infection. The dull, lumbar pain and reflex groin pain may simulate hydronephrosis, and if infection takes place, pyonephrosis. Some authors state that the cyst is composed of two layers of mucous membrane, that of ureter and bladder with fibrous or muscular tissue intervening.

TREATMENT.

Suprapubic or endovesical operation is always indicated, due to hydronephrosis or pyonephrosis. The former is usually present and less often the latter; both conditions are destructive to the kidney. Hydronephrosis is caused by pressure and pyonephrosis by destruction of the parenchyma and general infection.

The suprapubic operation consists of slitting the cyst and suturing the two layers, or complete resection of cyst with circular suture of mucous membrane. The endovesical operation is the one of choice, due to the improved endovesical technic. When endovesical operations were first used, some of the methods were successful and others were not. One method was to produce dilatation with ureteral bougies and catheters up to 12 F. and leaving them *in situ* for twenty-four hours, but this method often failed as recontraction took place. Sometimes the small meatus was slitted with cystoscopic scissors, and then dilated, biting off pieces of cyst wall with Young's cystoscopic rongeur. The following endovesical improved technic proved successful in my case, viz., the use of the D'Arsonval current as applied to bladder tumors.

URETER ANOMALY.

In doing ureteral work we should be on the lookout for anomalies of the ureters and kidneys. The unwary may be misled by finding the ureter orifices in normal position with functioning ureters. The supernumerary orifice being in some other part of the bladder hidden in the rugæ or trabeculæ of the vesical mucosa, or the ectopic opening of the aberrant ureter may be in the vagina or urethra, which makes it difficult to locate. In my case the supernumerary ureteral orifice was on the floor of the ureterocele, and was not discovered until the removal of the tumor, by the D'Arsonval current.

With our advanced diagnostic procedures it is possible to determine with accuracy the anomaly presented in this article, which, before the days of cystoscopy, were only found postmortem. This condition is one which confronts urologists in the proportion of about one to four.

A fused or double kidney usually accompanies a double ureter, and naturally permits of conservative surgery. Braasch says that when a double ureter is found, there is always a double pelvis and duplication of the kidney as well. Papin also states that even in unilateral duplication of the ureter, the pelvis is always doubled. Schwartz contradicts this, and Delmas is of the same opinion as Braasch and Papin.

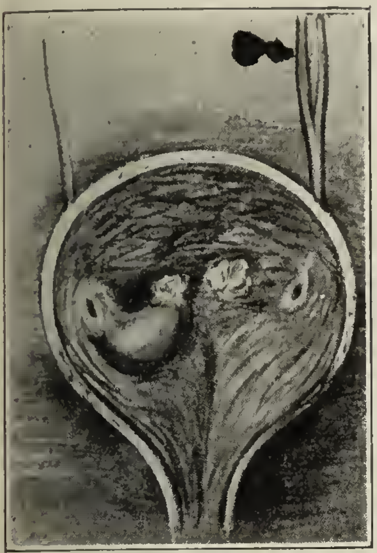

Fig. 1.

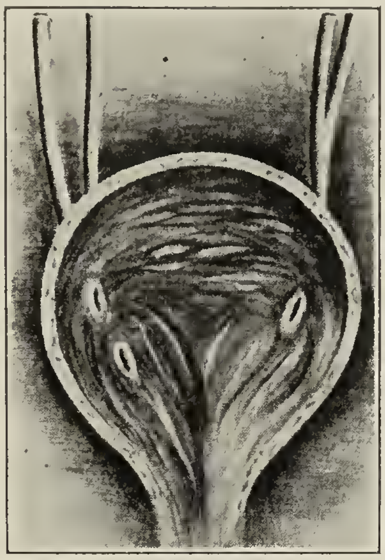

Fig 2.

Fig 1.—Shows ureterocele on right with normal ureter opening above; strawberry growths on summit, and a papilloma on bladder wall.

Fig. 2.—Shows the third ureteral opening after removal of the ureterocele.

A double ureter may unite at any point between the kidney and bladder and terminate in a single tube with a normally situated ureter opening in the bladder. Again when two openings are present in the bladder, the duplication is complete and ureters go to each segment of its kidney respectively. The lower segment is usually the larger and seems more prone to infection, whether because it is the shorter I do not know.

This anomaly of duplication of the ureter, according to Braasch, has no clinical significance of itself. It is only when some complication occurs that the recognition becomes of surgical and clinical importance. In the presence of such an anomaly, complications arise. It is, therefore, all important that the diagnosis should be made, which is possible today with our improved instruments and technic.

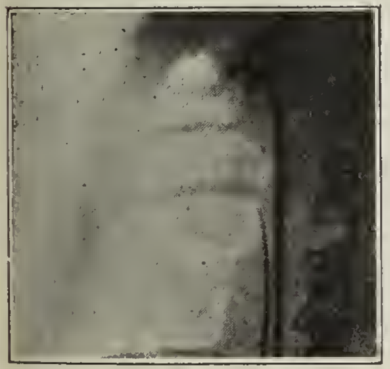

Fig. 3.

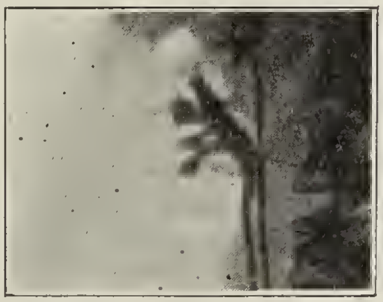

Fig. 4.

Fig. 3.—Shows pyelogram of upper and smaller segment.

Fig. 4.—Shows pyelogram of upper and lower segments.

The duplication may be unilateral or bilateral—but mostly unilateral. My case gave no symptoms referable to the left side and on cystoscopy showed the left ureteral orifice in normal position. The symptoms were pain over the right kidney and reflected to the groin with a previous history of cystitis. It is necessary for the up to date cystoscopist to have in mind these anomalies of the ureters and kidneys and be prepared with proper instruments, also up to date, backed with the knowledge of proper technic. Cystoscopy also revealed a tumor on the right side, the size of a hen's egg, which proved to be a ureterocele.

The condition is diagnosed by cystoscopic inspection—x ray, catheter, and the pyeloureterogram. If only one ureter opening is seen and is normal in appearance and position, the duplication is incomplete, by which I mean that the duplication takes place above the bladder, and the lead catheters, therefore, alone, will not make the diagnosis. A pyeloureterogram must be made. The duplicated orifices may be obscured by some pathological condition and will be found only after the removal of this, as was my experience, the supernumerary orifice on the right side was hidden by the ureterocele and was found only after its removal (Figs. 1 and 2). Therefore, the duplicated orifices are not always seen at the normal site. The two apertures may be in normal position and the supernumerary meatus in some other portion of the bladder or even in the urethra or the vagina, as previously stated.

Catheterization of the ureters is not difficult when only two apertures are present; the presence of a third or fourth makes it difficult with the ordinary catheterizing cystoscope, which must be introduced in the usual way with catheterization of one ureter and reintroduced for catheterization of the other two. Braasch has constructed a guide for the simultaneous catheterization of three ureters.

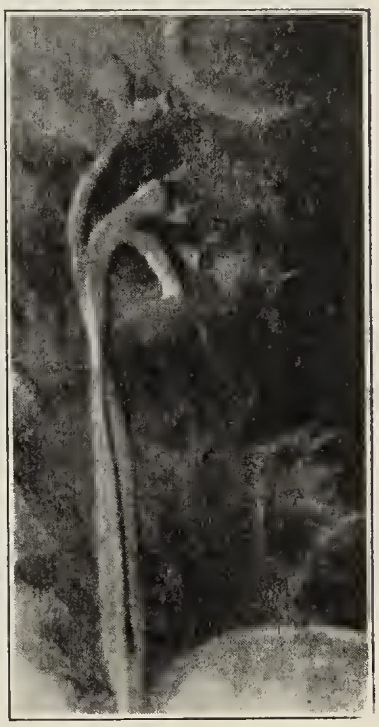

Fig. 5.—Shows double bifid ureter and double pelvis on left. The ureter bifurcates above the brim of the pelvis and a single ureter opening in bladder.

Functional tests of each segment can and must be done. Duplication may be confined to the kidney pelvis or to duplicate pelvis with separate ureters opening into the bladder (Braasch). Complications from duplication of the pelvis and ureters are hydronephrosis and pyonephrosis, tuberculosis, and stone. The most common is hydronephrosis and is due to obstruction.

It is not necessary to withdraw the ureteral catheter to the lower end of the ureter to make a diagnosis of the anomaly of a partial duplication of the ureter. The ureteropyelogram in this article will bear proof. It can be plainly seen that the x ray catheter is in the right branch of the kidney pelvis and the catheter is absent from the left branch. Yet both ureters are equally filled with pyelographic medium.

As to the duplicated pelvis, they may or may not communicate. This point can be determined by the methylene blue test. Functional tests of the duplicated segments are necessary, particularly when infection is present, to ascertain if heminephrectomy should be done. The pyelogram will show the distance between the two pelves, also their relative size.

CASE.—Miss A. K., aged thirty-six, was referred by Dr. Van S. because of a relapsing cystitis, pain in right kidney area, and reflexed pain to the right groin. Symptoms were of three months' duration; frequency by day seven to eight times, and twice at night. There were gastric symptoms. Physical examination was negative, except for the renal pain with reflex; no tenderness over either kidney, and no rigidity in costovertebral angles. Vaginal (bimanual) examination was negative, a discharge with pus cells was noted and a sterile specimen of urine obtained by catheter showed a specific gravity of 1.012, albumin negative, sugar negative, and an occasional pus cell.

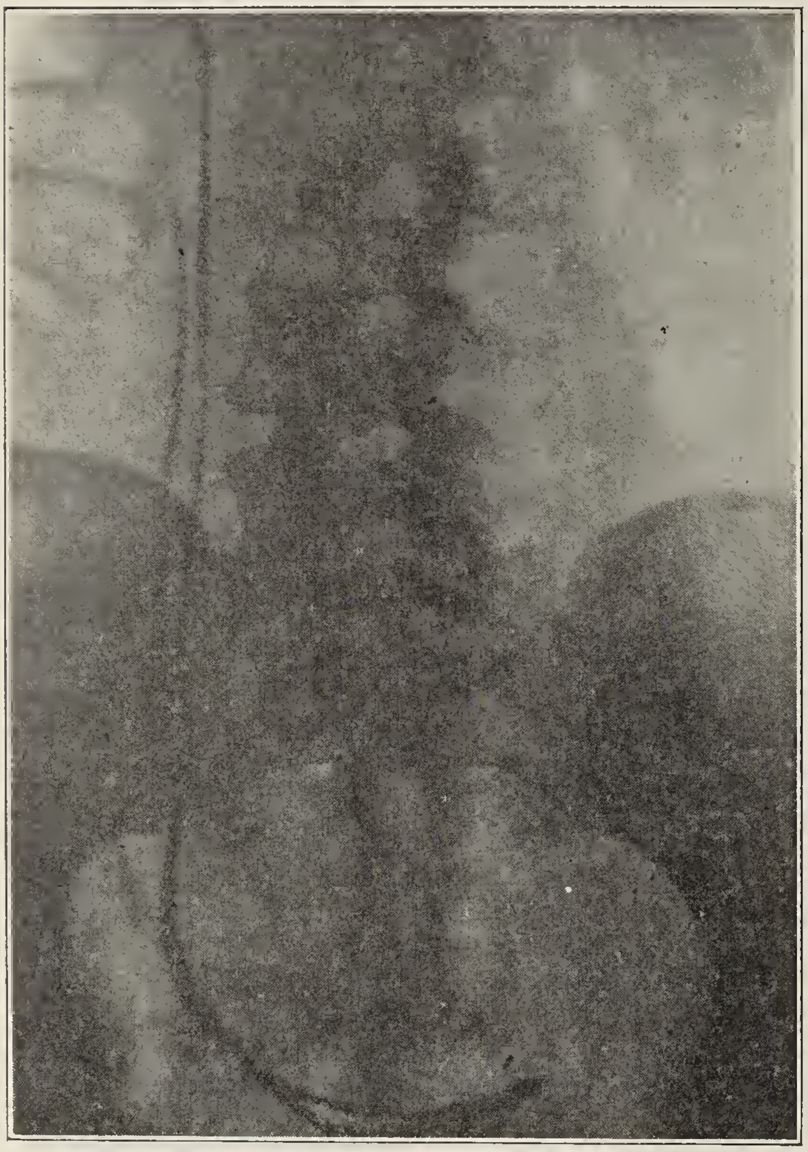

FIG. 6.—Shows catheter to each kidney segment after the removal of ureterocele; the opening of the second ureter was on the floor of the tumor.

Cystoscopy revealed evidence of old cystitis in the bladder mucosa. At the end of the ureteral ridge, just below the right ureter orifice, was a transparent tumor the size of an egg, which on close observation seemed to inflate and deflate. An area of erosion the size of a strawberry appeared on the summit of the tumor which bled easily and all attempts to find an opening on the summit of this growth failed. To the right of this growth was another small papilloma and also at margin of right normal ureter. Left ureter opening was normal in appearance and position.

Lead catheters were passed without obstruction to pelves of kidneys, and specimens collected for examination. Phthalein was injected intravenously; appearance of the dye, right three minutes, left three minutes, collection for fifteen minutes. Left kidney secreted twice as fast as the right. Pyelogram right five c. c., left twelve c. c.

Pyelogram showed on left side a bifid ureter and two distinct pelves—ureter bifurcates above brim of pelvis. Intravesical operation was performed for the removal of the tumor with the high frequency current. The tumor was well blanched and punctured.

The next sitting showed the walls of the tumor crater fashion, with opening on the floor, catheter inserted about ten centimetres. The walls of the tumor were sparked even with the bladder mucosa and the bladder irrigated with solution of silver nitrate.

The patient was told to report for further x ray and cystoscopy. The catheter was passed up each ureter opening on the right side to each kidney pelvis. The normal ureteral orifice was normal in size and position, the ureteral opening on the floor of the tumor was the larger of the two.

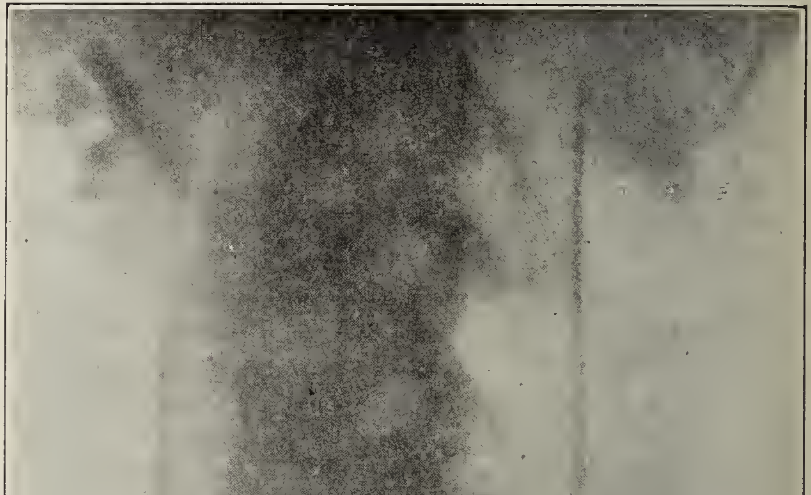

FIG. 7.—Showing pyelogram of lower segment of right double kidney and lead catheter without pyelograms on left. The small pelvis on the right suggests at once a double kidney. This plate was taken before the removal of the bladder tumor as seen in Fig. 1.

Specimens were collected from each segment; lower, cloudy; upper, clear. Pyelography of upper segment 10 c. c., lower segment 26 c. c. Radiogram shows catheter to each kidney segment respectively—the upper is the smaller of the two. Slight infection of lower segment and dilatation from inflammation. Cultures and stains were negative for bacteria. Direct smear negative for tuberculosis. Phthalein on right, eleven per cent. Operation (heminephrectomy) was not considered; patient improved, pains disappeared, there was gain in weight, appetite good, frequency disappeared. Patient is still under observation.

The diagnosis was bifid ureter on the left. Duplicate ureter on the right with ureterocele papillomata of bladder and right ureteral orifice. Two distinct kidney pelves on left and two distinct kidney pelves on right with beginning hydronephrosis in lower right segment.

An Unusual Case of Stone in the Bladder

By H. HALLARMAN, M.D.,

New York.

The following case is worth reporting, I believe, as it presents unusual features:

Case.—Mrs. R. M., aged twenty-three, consulted me on June 1, 1923, complaining of frequency of urination. Her family history was negative. As a child she had had measles, whooping cough, and chicken pox, from all of which she had made a good recovery. She never had had scarlet fever. Menstruation began at the age of thirteen and had been regular since. She had been three months married and her last menstruation was ten days ago. She never had had any vaginal discharge and no pain on urination. Her habits were good, she did not drink tea or coffee to excess, her appetite was good, bowels were regular, and she slept well at night.

About three years ago she applied for a life insurance policy and was rejected because of something wrong in her urine. She consulted several physicians who told her that she was suffering from kidney trouble and put her on a special diet. It was then that she became aware of the fact that the frequent urination that she had noted for so long was not a natural thing. Although she had seen no improvement she still kept up with the special diet. None of the physicians whom she consulted gave her a physical examination or suggested any radiological examination. Her husband, who brought her to me, I knew to be free from any venereal disease.

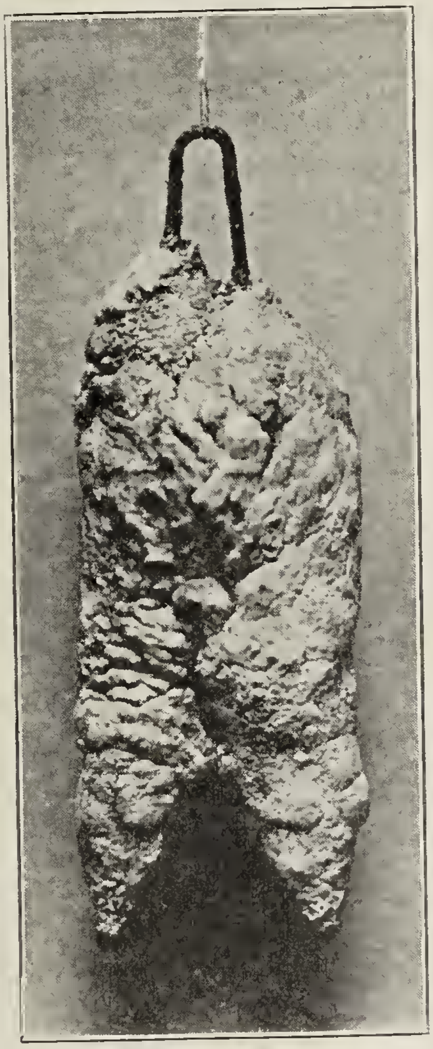

Fig.—Hairpin removed from bladder of patient. R. M.

Physical examination: Patient was a young woman twenty-three years of age, poorly nourished, skin clear, no edema anywhere, nothing abnormal in the head, neck, chest or abdomen, and no pain or tenderness over the kidney region.

Vaginal examination: A hard mass could be felt through the anterior wall of the vagina, and on bimanual examination it felt as if it was in the bladder. It was movable anteroposteriorly but not from side to side. No pain was elicited during the examination. The urine passed while in the office was turbid, bloody in appearance, specific gravity 1.022, albumin positive, reaction alkaline, sugar negative, indican normal.

Microscopical examination: Red blood and pus cells in abundance, no casts. Blood pressure was 124-80.

I made a diagnosis of a stone in the bladder. A cystoscopic and radiological examination by Dr. R. L. Dourmashkin corroborated the diagnosis, but it also showed a hairpin running through the centre of the calculus. On June 7, 1923, a suprapubic cystotomy was performed under nitrous oxide oxygen anesthesia by Dr. G. Warren. After freeing the free end of the hairpin from the posterior wall of the bladder the stone was removed. It weighed thirty grams. The calculus had formed around the ends of the pin resembling a huge bicuspid tooth, the head of the pin projecting free for a distance of one and a half centimetres. The whole stone was eight and a half centimetres long, three centimetres wide, nine centimetres circumference, two and a half centimetres at the points. Chemically it consisted of natural calcium phosphate and calcium oxalate. The patient made an uneventful recovery.

Comment: The pin must have been introduced into the bladder when she was a child, probably during masturbation. The size of the stone and its hardness leave no doubt that it had been there for many years. A physical examination, cystoscopy, and a radiological examination would have disclosed the nature of disease long before.

Editorial Articles

INDUSTRY AND VENEREAL DISEASES

The relation of venereal diseases to the industrial worker is treated in an article by Dr. J. J. Heagerty in a recent number of the *Canadian Public Health Journal.* Industrial physicians have estimated that the incidence among workers in industry of these diseases is from two to ten per cent., but, when intensive and systematic investigations have been conducted, these have shown that the rate is really higher. The ratio of gonorrhea to syphilis among laboring men has been found to be about four to one. That injuries are a precipitating cause of paresis in syphilitics has been generally demonstrated, and this fact should be realized and looked for in diagnoses of such cases. The nervous and cardiac forms of syphilis are the most dangerous, not only to the individual affected, but also to those with whom the syphilitic comes in contact in his work, if it be of a nature at all hazardous, such as that of the railroad engineer, the motorman or chauffeur, or the elevator operator. Such work demands oftentimes quick thinking followed by decisive action, and, since alertness and precision are greatly diminished in the syphilitic, the liability to accident is correspondingly increased. These forms of syphilis progress insidiously during the period of socalled latency, and so are frequently not recognizable until far advanced.

The article concludes with a plea that employers realize the great economic and vital loss from these diseases, and the highly beneficial results to be obtained, both for themselves and their employees, from periodical health examinations of workers. Laborers should also be instructed as to the dangers of the venereal diseases and the necessity for immediate treatment when such a condition is in its incipiency.

THE PRINCIPLES AND LAWS OF THE METHOD OF CLINICAL OBSERVATION

The principles of method of clinical observation were enunciated nearly twenty-five centuries ago by Hippocrates in the following celebrated passage: From the very onset examine the resemblances and dissimilarities with the state of health, the most considerable from their effects and the easiest to recognize, and which furnish all the means of observation; search for what can be seen, touched and heard; that which can be perceived when looked fo touched, smelled or tasted, and by using one's intelligence; lastly, that which can be made known by all known means.

What lends a real value to these precepts is that they are not merely the advice of a rhetorician but are the result of a long life of experience. Thus in treating the diagnosis of dislocation of the shoulder, Hippocrates insists on this elementary general medical rule which is invariably true, that one should "compare the healthy limb with the injured one in order to ascertain if that on the healthy side is dissimilar from that of the injured side," and he further says: "This is undoubtedly good advice but it can easily induce to error, which proves that it is not sufficient to know medicine theoretically, but that one should become familiar with this art by practice."

Therefore it is evident that facts, and facts only, interest the physician of Cos for he says: "The discourses and researches from which everyone should have for objects only those diseases from which everyone suffers." Besides, the physician should know what diseases arise in viscera, which are within, and which outside the body. He should also, in order to study human nature, "carefully ascertain the relations existing between man and his food and drink, his kind of life, and what influence each of these exercises on him."

Hippocrates likewise refers to the effects of baths and exercises and particularly reviews the action of seasons, winds, waters, soils and climates on disease. He points out that for him "the best physician is he who knows how to foresee" as "he will treat disease all the better when he is able by the present condition to foresee what is to come."

Hence, according to Hippocrates, medicine should be the study of 1, diseases themselves, their symptoms and sites; 2, their causes; 3, their evolution, prognosis and treatment. The three operations of Hippocratic observation have each their intrinsic value, as well as their own peculiar faults which are to be avoided.

If the knowledge of signs in the description of disease is an essential and necessary notion, it is clear that their endless subdivision—by multiplying details—tends to confusion. This is why Hippocrates rightly reproaches the physicians of Cnidos who "wishing to characterize the varieties of each disease with exactitude have gone astray."

The determination of the causes of disease is likewise an operation of great value but on the condition that one reasons on facts and realities and not on hypothetical estimates or imaginary generalizations. It is precisely this defective reasoning that Hippocrates brings into relief in all who have attempted to discourse upon medicine taking as a basis: "the hypothesis of either hot or cold, moist or dry or any other agent of their choice." And he adds: "They simplify things but are all the more to be blamed because they deceive themselves."

Finally prognosis is a fundamental operation of the medical mind and Hippocrates especially insists on this point and again points out that "he who would learn to conjecture properly what affections are recovered from and those with a lethal outcome, those which last a few days or a longer time must judge all things by the study of symptoms and by the comparison of their reciprocal value."

These symptoms as described in the treatise on prognosis are derived from the aspect of the patient's face and his position in bed, fever, sleep or delirium, pain, respiration, vomiting and sputum, the urine and feces as well as examination of the throat, thorax, abdomen, etc. All this requires special care on the physician's part, and Hippocrates blames the physicians of Cnidos who are content with simple data furnished by the patients themselves in reference to their illness. Hippocrates points to the fact that the ancients wrote nothing on diet which he regards as a serious omission. Hence he enters into great detail of food, especially the decoctions of barley—recently brought into modern therapeutics by Springer and others—and the methodical use of drinks, among which figure sweet, strong, white and red wines.

SURGICAL TUBERCULOSIS AND THE WASSERMANN REACTION

When one reads the classical descriptions, the diagnosis of bone, joint and lymph node manifestations of tuberculosis would seem to be an easy matter or at least possible to make in the average case. Nevertheless it not infrequently happens that a symptom, localization, a sign found in the general examination of the subject or the evolution of the affection do not correspond to the ordinary clinical picture of tuberculosis and lead one to suspect syphilis. But here again the clinical differentiation between the bone joint and lymph node manifestations of tuberculosis and syphilis is difficult and it has been this difficulty that has led of late to resort to the Wassermann reaction.

At Berck-sur-mer, Pouzin and Stroehlin have recently used the Wassermann in two hundred and twelve children presenting lesions of the joints, bones or lymph nodes which they classify under three headings. The first group comprised children offering stigmata of congenital syphilis and a close study at the hospital resulted in a diagnosis of syphilis before the laboratory result was known. The second group comprised children whose affection presented one or several symptoms which did not correspond to the ordinary clinical picture of tuberculosis. They were cases of suspected syphilis. The third group was made up of patients whose local or general clinical examination gave rise to no suspicion of syphilis; they were regarded as cases of confirmed tuberculosis before having been submitted to the Wassermann test.

The Wassermann made in the three groups gave the following results. In the first group there were twenty-one positive and four negative, otherwise eighty-four per cent. positive results. In the second group there were fifteen positive and forty-nine negative, otherwise 29.4 per cent. positive. In the third group there were eight positive and one hundred and fifteen negative, otherwise 6.5 per cent. positive.

In the patients of the first group, the Wassermann test allowed one to begin or to continue antisyphilitic treatment. In the second group it allowed one to affirm syphilis in fifteen cases in which it could only be suspected. Finally, in the third group, which clinically appeared to be entirely tuberculous cases, the Wassermann was the only means of detecting syphilis, a diagnosis which afterevents confirmed and led to an appropriate treatment followed by a rapid recovery.

The Wassermann reaction should be closely united to the clinical diagnosis of surgical tuberculosis. By this means a clinically certain diagnosis can be verified, signs leading one to suspect syphilis can be confirmed while errors in diagnosis are revealed. In some cases that are impossible to diagnose clinically, it may be the means of indicating the veritable origin of the affection.

ARCUS SEMILUNARIS OF THE NAILS AS A DIAGNOSTIC SIGN OF SYPHILIS

It may be well to draw attention to a diagnostic sign first described by G. Milian of Paris, in 1913, which consists of a rose red semicircle conforming in outline to the free edge of the fingernail and four to five millimetres behind it, when the nail is pared close. Its concavity similarly accords to the lunula. The convexity is sharply defined, the concave margin more blurred. It is one half to one millimetre thick. It is frequently separated from the lunula by a white semicircle which makes it evident. It is more common on the middle and ring fingers, less so on the thumb, and it may be present on both hands.

Unlike other lesions of the nails it does not shift with their growth, the reason being quite simple, it merely being that the sign is the result of a deposit of treponemata in the capillary circulation at the point of insertion of the nail upon the subjacent derma where this is, so to speak, a capillary dead end. Active antiluetic treatment will cause it gradually to retrogress if sufficiently prolonged but it will survive the transformation of a positive to a negative Wassermann reaction. In ten years Milian has not noticed this sign in other than syphilitic subjects and has met with it in the third or fourth year of the infection in persons who, before contracting syphilis, were free from it. This sign may appear during the first year of the process but is more prone to arise in neglected cases. It also develops in congenital syphilis.

As to the application to diagnosis, Milian cites the case of a patient with a preputial sore and papules. Every evidence of an ulcus molle was present and none of syphilis; even the Wassermann reaction was negative. However, the patient clearly showed the nail sign. Under antisyphilitic treatment the papules healed in four or five days and the sore in a couple of weeks, although it had existed that same length of time with no sign of remission before the patient applied for treatment. The nail sign is an indication of active syphilis and therefore of the need for active treatment. To cause the sign to disappear will, in most instances, require some eight months.

VENEREAL DISEASE CONTROL IN THE STATES

In the recently published transactions of the Twentieth Annual Conference of State and Territorial Health Officers with the United States Public Health Service, held in Washington in 1922, the program for the State control of venereal diseases proposed and approved is given in full. One point emphasized was the value of devoting considerable thought, energy, intelligence and supervision to the question of interesting private practitioners throughout the country in venereal disease control and of endeavoring to see that these doctors give better treatment to such cases than they have done in the past. The belief was expressed that ninety per cent. of such cases would be treated by general practitioners, not by specialists. It was also urged that the importance of the social side of venereal disease should be emphasized, as this phase is not appreciated at the present time. The principal methods of doing this would be to ascertain sources of infection and to inaugurate efforts to prevent the spread of the diseases.

It was agreed that the work of the divisions of venereal diseases in the various State boards of health should be linked up with the work to be done in each State under the terms of the Sheppard-Towner Act. Just how to accomplish this linking up of venereal disease control with infant and maternity welfare work would be something for each health officer to work out for himself. Another point agreed upon was that every effort should be made to develop the control program as a local, community responsibility. Each town and county of every State should bear its own financial burden and provide treatment for infected persons, and should carry on its own preventive, protective, and educational work, just as it does in the case of the other communicable diseases, as a part of the work of the bureau or division of communicable diseases. In this connection it was recommended that more attention be paid to the sources of infection, especially houses of prostitution. Health departments must assume certain responsibilities in connection with eliminating vice conditions in the community if syphilis and gonorrhea are to be treated like other communicable diseases.

Recommendation was made that a vigorous educational campaign for informing the public should be carried on, with more definite emphasis upon venereal diseases than has been the case in the past. This should be extended to the schools, through cooperation of the State boards of health and education, which should furnish exhibit material, lectures, and other kinds of instruction of the proper kind. Another fertile field for extending public education on the subject would be through the many institutes and conferences of laywomen held annually in all the States, and the social hygiene conferences throughout the country.

It was announced that the conditions of receiving the allotments from the Government for the work in the States are that an equal amount must be appropriated or otherwise set aside by the State and evidence furnished that this has been done, and that a budget must be prepared and forwarded to the Public Health Service showing the manner in which it is proposed to expend this joint fund, after which the quarterly allotments will be paid in advance.

THE NEW YORK INFIRMARY FOR WOMEN AND CHILDREN

The recently issued annual report for 1921 of the New York Infirmary for Women and Children covers the sixty-fourth year of its existence. The first annual report, a small and modest document issued in 1855, tells of a hard struggle under heavy financial odds to establish a hospital where medical women could obtain training, and where destitute and friendless women could have help and care. In 1853, a small room in a poor quarter near Tompkins Square was rented and a dispensary opened. Later this establishment was moved to Third Street. In 1857 a step in advance was made by renting a house at 64 Bleecker Street, which was equipped as a hospital for the reception both of patients and of young assistant physicians. This institution, under the name which it now bears, was opened formally in May, 1857, by the Rev. Henry Ward Beecher. The New York Infirmary for Women and Children holds the honor of being the first hospital in this country dedicated to the service of women and children and the training of women physicians. In the early days when the founders, Dr. Elizabeth Blackwell and Dr. Emily Blackwell, saw the first need for such an institution, they were told, to quote from the former's book, *Pioneer Work for Women,* that "female doctors would be looked upon with so much suspicion that the police would interfere; that if deaths occurred their death certificates would not be recognized; that if any accident occurred, not only the medical profession but the public would blame the trustees for supporting such an undertaking; and, finally, that they would never be able to collect money enough for so unpopular an effort." To quote from the 1921 report: "The world has moved a long way since then. In the year 1921 . . . the institution cared for 1,672 sick women and children. The outpractice of the infirmary showed 4,572 visits. The maternity service, which has possibilities of becoming one of the largest maternity services in the United States, cared for 452. The prenatal clinic was begun more than thirty years ago. This work is now being introduced into various districts of the city by the Board of Health. So runs the tale of one of the most courageous and successful pieces of pioneering ever accomplished by men or women."

NEW BUILDING FOR JEFFERSON HOSPITAL

The latest annual report of the Jefferson Hospital in Philadelphia announces the completion of plans for a new fourteen story addition now under construction. The site is that of the old hospital, which has been used for the last several years as a nurses' home. The plans call for the most modern type of building, with all the best and latest specifications for hospital construction. There will be three surgical operating rooms and two delivery rooms on the fourteenth floor, with a surgeons' dressing room, anesthetizing rooms, nurses' work rooms, and a sterilizing room adjacent to the operating rooms. The eighth, ninth, tenth, eleventh, twelfth, and thirteenth floors will contain each nineteen private rooms, and a service room, diet kitchen, and nurses' office. The third, fourth, fifth and sixth floors will be used as quarters for pupil nurses until a new nurses' home can be built. The plans of these rooms will be such as to make them convertible when necessary into rooms or wards for patients. On the second floor will be located additional x ray rooms, the dental clinic, and the bronchoscopic clinic. The first floor will contain offices, a staff room, the social service department, and occupation therapy rooms. The clinical amphitheatre will occupy part of the basement and the first and second floors, and will have a seating capacity of five hundred. The basement will contain also an anesthetizing room, surgeons' dressing room, sterilizing room, and the neurological, orthopedic, clinical medicine, and gastroenterological outpatient departments. There will be an enclosed roof garden on the top of the fourteenth floor.

IN MEMORIAM: WARREN G. HARDING

President of the United States, 1920-1923.
Honorary Vice-President of the National Tuberculosis Association, 1921-1923.

By S. Adolphus Knopf, M. D.

Obituaries by the thousands have been written for American and foreign newspapers on the death of one of the most beloved, honored, and distinguished Presidents of the United States. All have emphasized the unusual qualities of Warren G. Harding as a man, a statesman, and a lover of his kind. His splendid physical appearance, his congeniality, his warm heartedness and his sympathy with all great and noble causes, have won him countless friends and admirers.

All this has been well expressed by the public press; but strange as it may seem, in no one of the obituaries has there been any mention of the great and special interest President Harding took in medicine. Nevertheless, one might say that he belonged to a distinctly medical family; his father, brother, and nephew are successful physicians and there can be no question that the personal qualities this great man possessed were those which would have made the ideal physician. Of Warren G. Harding's boyhood an unknown biographer said: "He was just a natural, healthy, robust boy, endowed with the supremest gifts of nature—good, hard common sense, a rugged constitution, a sunny disposition, and a heart full of the milk of human kindness." What better foundation and qualifications could there be for a medical man? But, of course, it was fortunate that young Warren should have chosen the career which made him one of the greatest Presidents of the United States and now his loss is felt throughout this country and the civilized world.

From his humble home in Marion and the time when he printed his own home newspaper until he reached the exalted position of the first executive of the Republic, President Harding kept his inherited love for medicine, his admiration for medical science, for our great specialists, and, above all, his genuine appreciation of the service rendered by the general practitioner as family or private physician. He took with him to Washington his own family physician, Dr. Sawyer, and honored him by conferring upon him the rank of a Brigadier General. An equally gracious act, showing what the President thought of the value of a medical man as an ever ready adviser and friend in time of illness and showing also the greatness of the man, Harding, and his sympathy for the sick and suffering, was manifested in the following incident: At the time of President Wilson's retirement from office, it is now well known that he was a seriously ill man. Admiral Grayson was Mr. Wilson's private physician and that the invalid might not be deprived of this valued medical adviser, one of President Harding's first official acts was an order that Admiral Grayson should not be assigned to any duty which might demand his leaving Washington and giving up the care of his illustrious patient. This was unknown to ex-President Wilson and unknown to the outside world, and only now, after all that is mortal of President Harding has been laid at rest, do we learn of this touching incident.

To the tuberculosis workers and sanitarians, the late President was very close indeed and he expressed his deep interest in these subjects publicly on more than one occasion. On September 27, 1921, after having presented a silver cup to the children of the District of Columbia, in the intercity contest of the Modern Health Crusade, the President wrote to Mr. Charles M. DeForest, of the National Tuberculosis Association, as follows:

> My Dear Mr. DeForest:
>
> I was very much interested today in presenting, on behalf of the National Tuberculosis Association, the silver cup won by the school children of the District of Columbia because of their larger enlistment, relatively, in the Modern Health Crusade, particularly in their enlistment to make effective warfare against tuberculosis. I may quite sincerely express the hope that in every American city and country district a like large proportion of boys and girls will make themselves knights by faithful attention to their own habits and their care and concern for the health of the nation.
>
> Very truly yours,
> (Signed) Warren G. Harding.

This letter shows not only Mr. Harding's great love for little children but also his deep interest in their physical wellbeing and the health of the nation at large. In his love for little children and their welfare, the President had a most devoted sympathizer and helper in Mrs. Harding.

President Harding took a particular interest in the tuberculous exsoldiers and it is to him that we are very largely indebted for the energetic provision for the care and treatment of our sick and wounded exsoldiers now carried on so effectually by the War Veterans' Bureau.

On March 1, 1922, when learning of the contemplated publication of the History of the National Tuberculosis Association, he wrote to the author as follows:

> I am glad to receive your communication, with enclosures, and to learn that the National Tuberculosis Association has undertaken the publication of a History of the Antituberculosis Movement in the United States.
>
> My attention has been recently directed to the beneficent results achieved by the intensive antituberculosis effort, as evidenced by Dr. Frankel's paper at the annual meeting of the National Association last June. It is certainly gratifying to know that sixty thousand fewer deaths occurred in the United States Registration Area from pulmonary tuberculosis in 1919, than would have occurred if the 1900 death rate had prevailed. The knowledge of such impressive facts cannot fail to be an inspiration to all engaged in preventive medicine and in the mitigation of human suffering and distress.
>
> With all good wishes for the continuing success of your efforts, I remain,
>
> Yours sincerely,
> (Signed) Warren G. Harding.

Those of us who had the rare privilege of meeting the President at the annual meeting of the National Tuberculosis Association in 1922, will never forget the cordiality with which he greeted the many members who were presented to him. For each one he had a smile, a kind word, and a grasp of the hand.

Now we all bow our heads in sorrow for the loss of our great President who by word and example has shown us where our duty lies in future work. May his name be to us the symbol of duty and inspiration to go ever onward in the fight, not only against the great white plague, but against all preventable and curable diseases, and make the people of the country he loved so much the healthiest, happiest, and physically and morally strongest nation of the world.

News Items.

Health Expert Arrives.—Dr. G. Sanneman, in charge of the Public Health Service of the port of Hamburg, arrived in this country to spend a month studying methods of the United States health officers at the Quarantine Station, Staten Island. He said he would also inspect Ellis Island.

Voronoff to Bare Operation Secrets.—Dr. Serge Voronoff has accepted the invitation to attend the Second International Congress of Comparative Pathology, to be held in Rome, October 7th. Dr. Voronoff says he will then for the first time give the details, methods, and results of gland operations he has performed on forty-five men.

Dr. Maude E. Abbott Accepts Post.—Dr. Maude E. Abbott has accepted the chair of pathology and bacteriology at the Woman's Medical College of Pennsylvania. Dr. Abbott comes to Philadelphia direct from McGill University, Montreal, Canada, where she was the recipient of most of her world honors.

Fund for Child Health.—The American Child Health Association has announced the establishment of a $10,000 scholarship fund to be awarded to physicians now engaged in child health work for study in medical centres or for travel and observation of child hygiene work. The association has created two similar endowments within the last six months. The purpose of the third appropriation is to meet the growing demand for more and better trained physicians in the field of child hygiene.

Röntgen Ray Society Convention.—The annual convention of the American Röntgen Ray Society is to be held in Chicago from September 18th to 21st. A number of eminent foreign contributors will appear on the program, and the treatment of patients by high voltage x ray will have a prominent place on the program.

Applied Dental Science Annual Meeting.—The fifth annual meeting of the American Academy of Applied Dental Science will be held in Cincinnati, Ohio, January 7 to 9, 1924. All students of progress in both the dental and medical professions are invited to attend these sessions. For further information write Dr. E. F. Forestner, 104 Bell Block, Cincinnati, Ohio.

American Electrotherapeutic Meeting.—The American Electrotherapeutic Association will hold its thirty-third annual meeting September 18th to 21st at the Hotel Chalfonte in Atlantic City. All licensed physicians interested in physiotherapy are welcome. Of especial interest on the program will be a symposium on physiotherapy in general practise. Programs can be obtained from the corresponding secretary, Dr. Richard Kovacs, 223 East Sixty-eighth Street, New York City.

Medical College to Establish Clinic to Study Children.—A clinic for unruly children, the second of its kind in the world, will be established at Rush Medical College in Chicago. The new clinic at Rush will specialize in neurotic children between the ages of three and fourteen years. Its nurses and physicians will investigate home conditions first. The only other clinic in the world specializing in the behavioristic problems of children is in Boston.

International Union Against Tuberculosis Meeting.—The council of directors of the International Union Against Tuberculosis held its annual meeting in Paris on July 26, 1923, at the headquarters of the League of Red Cross Societies. Twenty members of the council from different countries met under the presidency of Dr. Dewez, of Brussels. The report of Prof. Besançon, of Paris, on the question of the "respective value of technics for research of Koch's bacillus for diagnosis of lesions in human tuberculosis" gave rise to an interesting discussion. A report of this discussion will appear in the next number of the *Bulletin of the International Union Against Tuberculosis*.

International Surgical Congress Meeting.—At the congress recently held in London, Dr. Davide Giordano, Venice, Italy, was elected president to succeed Sir William Macewen. The predecessors of Giordano in the presidency of these congresses were Dr. Kocher of Berne, Dr. Czerny of Heidelberg, Dr. Lucas Championnière of Paris, Dr. Depage of Brussels, Dr. Keen of Philadelphia, and Dr. Macewen of London. The *Riforma Medica* states that Giordano is the first president who is not connected with a university. The toast to the delegates at the annual banquet was acknowledged by Dr. Crile, for the United States; Dr. Koch, for Holland; Dr. Mayer, for France and Belgium; Dr. Alessandri, for Italy; Dr. Hansen, for Denmark; Dr. Kayser, for Sweden; Dr. Petridis, for Egypt; Dr. De Zawadski, for Poland, and Dr. de Quervain, for Switzerland. The next congress will be held in Rome and not in Warsaw as had been proposed.

Poor Will Get Insulin Free.—Persons in Ontario suffering from diabetes and unable to pay for insulin will be provided with the remedy free of charge by the Ontario government.

Academy of Medicine on Vacation.—It has been announced that the New York Academy of Medicine will be closed during the last two weeks of August in order that the building may be renovated. This is the first time, in at least thirty years, that the academy has been closed to the public so long.

Dr. Lowsley Sails.—Dr. Oswald S. Lowsley, managing director of "Diamond Jim" Brady's million dollar foundation for research in urology at the New York Hospital, sailed recently aboard the *Leviathan* to attend clinics in Paris, Vienna, and Rome, where he hopes to acquire new ideas in connection with operations that lead to rejuvenation.

Gouraud Decorates Dr. Harvey Cushing.—The medal of Chevalier of the French Legion of Honor was conferred upon Dr. Harvey Cushing, the Boston surgeon, by General Henri Gouraud during the French war hero's visit to Harvard University. Dr. Cushing received his decoration for his services in France in 1915.

Hail Insulin's Discoverer.—The members of the British Medical Association forgot their professional dignity and cheered heartily again and again for the young Canadian, Dr. F. G. Banting, of Toronto, when he was introduced to them to tell the scientists about his discovery of insulin for the treatment of diabetes.

Physician Undergoes Steinach Operation.—Reduction of high blood pressure and the retardation of arteriosclerosis can be accomplished by means of the Steinach rejuvenating operation, according to Dr. David Trumball Marshall, of Villard Avenue, Hollis, L. I., who admitted he had undergone the operation at the Central Park West Hospital.

Maternal Hospital New Building.—The Jewish Maternity Hospital has purchased four lots at the northeast corner of Fifth Avenue and 108th Street, where it plans to build a new twelve story hospital building, which, when equipped, will cost about $1,000,000, and provide 150 beds. Most of the necessary funds have been subscribed.

Hay Fever Clinic Opens in Brooklyn.—A new department of diagnostic research at the Victory Memorial Hospital, Seventh Avenue and Ninety-second Street, Brooklyn, has been established. It offers free scientific diagnosis to sufferers from hay fever, asthma and kindred ailments. Applicants, after expert examination, will be sent back to their family physicians for treatment.

Dr. Voorhees Publishes Book.—Dr. Irving Wilson Voorhees, who has a large medical practice among singers in New York, and who is adviser to members of the Metropolitan, Chicago and Century opera companies, has written a book on *The Hygiene of the Voice*, which Macmillan is to publish next month. The book has grown out of the author's experience in examining and treating singers and speakers, and in it he deals with the singer's problems especially from the point of view of the voice physician. Dr. Voorhees is assistant surgeon to the Manhattan Eye, Ear, and Throat Hospital.

LONDON LETTER.

(*From our own correspondent*).

London, *July 9, 1923*

CANCER AND CIVILIZATION.

Sir Arbuthnot Lane sent to the lay press recently, the following contribution on the cancer question, a question which owing to the vigorous public propaganda just launched in great Britain is arousing much interest among all classes of the community. Sir Arbuthnot says:

"It seems to me that the question of the causation of cancer has been rendered much more complex than is necessary. Nature has provided us with most definite evidence as to the cause of cancer, or, rather, as to the circumstances in which cancer does or does not occur. In native races in their normal surroundings cancer and the intestinal conditions which precede it are absolutely unknown. In civilization cancer and the associated intestinal conditions appear for the first time and are most prevalent. We believe that they are increasing with great rapidity, exacting a steadily increasing toll of human life. If the native is removed from his normal surroundings and habits and becomes a member of a civilized community, he is affected by cancer and the associated intestinal conditions with the same frequency as the white man with whom he lives. Indeed, the prevalence of cancer in the native varies directly with the degree of civilization in which he is thrown. Of the truth of this we have absolute evidence. It merely remains for us to determine the nature of the variations in the relationship of the individual to his surroundings which exist in the savage and in civilized man, and to endeavor by some means to approximate the habits and diet of the cancerous races to those of the cancer free races. An enormous amount of money has been expended in investigation of minute detail with practically little or no results. It is unfortunate that as a special sense develops one appears to lose one's common sense."

If the occurrence of cancer can be largely prevented by regulating the diet and habits of life so that intestinal conditions are such that they do not tend to act as exciting causes of cancer, these means of prevention ought to be encouraged. The prospects of grappling with cancer successfully are more hopeful now that the public is beginning to manifest an interest in the subject. It is well, therefore, that all aspects of the matter should be presented to the public in the lay press for it is only by these means that a general concern in all classes of the community can be effectively excited.

CAUSES OF SUICIDE.

Speaking on True Temperance at the 1912 Club recently, Mr. Danford Thomas, a well known London coroner, said that people were fond of saying that suicides were chiefly due to alcohol, but in his experience of twenty years as a coroner that certainly was not true. He found that suicides were more often due to lack of money and to domestic trouble. Sometimes these persons when in trouble took refuge in alcohol, but in the primary state he considered that alcohol was a very slight cause of suicide. It was one or two per cent., and not more. He knew of two medical men who, after having drunk heavily all their lives, suddenly became fanatical advocates of temperance, because they could drink no more.

UNIVERSITY OF LONDON.

At a meeting of the Senate of the University of London, on June 20, last, Mr. H. J. Waring, M.S., F.R.C.S., was reelected Vice-Chancellor for the year 1923-24. Professor Frederick Wood Jones, D.S.C., M.B., B.S. (Lond.) was appointed as from September 1st to the University Chair of Anatomy, tenable at St. Bartholomew's Hospital Medical College. Since 1919 he has been professor of anatomy in the University of Adelaide. Mr. R. J. S. McDowall, M.B., Ch.B., D.S.C. (Edin.) was appointed as from August 1st to the University Chair of Physiology, tenable at King's College. He has been lecturer in physiology at Edinburgh; and since 1921, he has been lecturer in experimental physiology and experimental pharmacology at Leeds. Mr. Gilbert Stead, M.A. (Camb.) was appointed to the University Readership in Physics, tenable at Guy's Hospital Medical School, as from August 1st.

CHILD WELFARE IN SCOTLAND.

In all parts of the civilized world child welfare is beginning to be estimated at its true importance. In an industrial country, as in the United Kingdom, it is absolutely essential that infants should be born and reared under as favorable conditions as possible, including antenatal care, because the well being of a country rests upon the physical and mental health of its workers. In a country such as the United Kingdom in which more than three quarters of its population live in towns densely inhabited, often greatly overcrowded, and in which a large proportion of the inhabitants are engaged in industrial pursuits, most of which are unhealthy in varying degrees, the problem of rearing infants and children in a healthy manner is of more importance and more difficult of solution than in any other civilized country.

Last month there was opened at Motherwell, near Glasgow, the Carnegie Child Welfare Centre and Maternity Home, which is intended to provide instruction in hygienic principles to those who are in charge of infants and young children. The cost of the building was borne by the Carnegie Trust and the equipment by the local authorities with the aid of Government grants. At the opening ceremony Sir Leslie Mackenzie, M.D., said that the reasons why Motherwell had been chosen for the experiment were its phenomenal rise in fifty years from a village to a town of seventy thousand inhabitants, its possession of a really active local authority, and its central position. If they had an education centre which was to be a visitation spot for the whole world, it must be a place easy of access.

THE SMALLPOX EPIDEMIC.

Smallpox is still prevalent in Gloucester and neighborhood and cases of the disease have been reported in Derbyshire and in other parts of the country. The type of the disease is mild, so mild indeed that many cases were undetected and no precautions taken to prevent the infection from spreading. However, every effort is now being put forth to curtail its dissemination. The epidemic at one place or another has been in existence since last autumn and affords a striking object lesson on the results of the neglect of vaccination.

As has been emphasized on more than one occasion in these letters, Great Britain, the land in which vaccination was discovered, is almost the only civilized country in which vaccination against smallpox is almost a dead letter. A loophole for the ignorant and indifferent to escape vaccination is provided by the conscientious objectors' clause of the vaccination act. Liberty is so greatly valued in this country that even the ignorant and careless must not be compelled to protect themselves and their children from a dangerous disease and what is of more consequence to avoid spreading it, because forsooth, they do not wish. The value of measures to promote good health is not appreciated and measures of a preventive nature are viewed askance and even with a certain amount of derision by the mass of the people.

In the past the medical profession has neglected its duty of teaching the public and does so still. In this country medical ethics stand in the way, for if a medical practitioner posed as a teacher of the public he would be stigmatized by his fellow practitioners as an advertiser and perhaps rendering himself liable to action by the Medical Council. And yet there should be means found to counteract the teachings of the opponents of vaccination, of medical research, of hygiene, and of many other methods which lead to good health and its maintenance. The public is taught many untruths concerning preventive and remedial medicine and it behooves the medical profession to devise ways of teaching the truth. The day is past for holding the view that many medical men still hold that medical matters should be discussed only in medical circles and societies. For the sake of the public as well as of the profession, a more broadminded view and one more in keeping with the trend of the times should be taken and the public should be made to know that good health is of greater importance than politics.

THE MINISTER OF HEALTH ON CANCER.

Mr. Neville Chamberlain, Minister of Health, on June 25th, last, made a speech in the House of Commons on health matters. He said that cancer was fourth on the list in England and Wales as regards mortality and accounted for about ninety-six in one thousand of all deaths from all causes. He was sorry to say that this disease was increasing among the English people. In 1900 cancer deaths to the million of the population were 829; in 1910 they had risen to 967, and in 1921 to 1,215. Two allowances must be made. The first was that methods of diagnosis were constantly improving. Then the fact that people lived longer than formerly brought a larger proportion of the population into that comparatively short span which was called the cancer age. Cancer was most prevalent between the ages of fifty and sixty. He had at the Ministry of Health a Standard Medical Committee on Cancer which advised him from time to time. Researches were being undertaken by three bodies, the Cancer Research Fund, the Middlesex Hospital and the Cancer Hospital. In addition the subject was constantly under the attention of the Medical Research Council and in the last few weeks another body had started, the British Empire Cancer Campaign. If that new body could succeed in cooperating with the existing bodies he, the Minister of Health, would be glad to give it his support.

VIENNA LETTER.

(From our own correspondent).

VIENNA, *May 13, 1923.*

HOW TO TREAT PATIENTS OF ADVANCED AGE.

Dr. Helmuth, lecturer on clinical medicine in Graz, read a paper on how to treat patients of advanced age, at a recent medical meeting. He said that the most important changes of advancing age affect the circulatory apparatus, as well as the vessels of the heart, and not infrequently the whole system is affected by an arteriosclerotic process. Naturally, the other organs and tissues also undergo the changes of old age. The most important of all pathogenetic signs is the failure of powerful reaction against external and internal damage. When all the other signs of fever are present there is no marked rise of temperature. With increasing age infective diseases give place to the diseases of tissue change that run a chronic course. The reason further lies in acquired immunity due to the cells overladen with products of tissue change affording an unfavorable soil. If infection occurs, as, for example, pneumonia, this runs in old age quite a different course from that in a young man. The rise of temperature is but slight, the sputum is rarely characteristic, the expectoration slight, the slight acceleration of respiration frequently the only objective sign of some disease of the respiratory tract. The changes in the central nervous apparatus due to the intoxication are foremost in importance, (mild delirium, etc.).

In old age almost all kinds of pathogenic bacteria may set up pneumonia. But the diplococcus decides the course rather than the form. In infective diseases, in the old, the excretion of noxæ through the kidneys, intestines and skin is arrested. A condition of chronic poisoning arises that manifests itself in increasing weakness, especially of the circulation.

In the matter of treatment, above all things the circulation must be excited. The equivalent of this is absolute rest; that position is the best that is the most agreeable. Further, warmed pure air must be provided, cooling of the body must be prevented by warm clothing, and the temperature of the room should be at least 180 C. Centripetal rubbings, friction with hot dry cloths, raising of the extremities influences the various stases, hot foot and hand baths with mustard, hot partial washing of the skin, moist partial packings are an important support. Warm baths in old age are less suitable on account of the extraction of heat. Mild massage is very stimulating to the circulation. Care should be taken of the bowels, and warm applications are useful in the stimulation of the abdominal circulation.

Too free feeding should be avoided as it burdens the heart and vessels. Medicaments are best given subcutaneously; the caffein salt or camphor oil are the best, with if necessary, the addition of ether. Digitalis, as a rule, is not well borne. Frequently, however, the end is attained by giving strong coffee or tea, with the addition of brandy or alcoholic drinks. Food must be given often and little at a time, more fluid or pultaceous than solid, more hydracarbons and fats than albumen. The old man lives through the administration of the daily amount of calories, and one day without food brings about a loss of power that may never be made good again.

The mouth and pharynx should be cleansed with borax and glycerine as aphthæ are apt to develop. The food should be given warm and the solid parts minced. Spices and salt should be given freely; alcohol also on account of its stimulating action. Food is best given in the shape of well cooked meats, sugar, milk and cream. The required amount of albumen, sixty to eighty grams, is best given as an addition to the milk in the shape of some nutritive preparation. If necessary, food should be given by the rectum.

EYESIGHT OF VIENNA BOARD SCHOOL CHILDREN.

The result of the systematic investigation of the eyesight of children attending the Vienna Board Schools, carried on since October, 1922, by eight ophthalmic surgeons, goes to show that among the boys six per cent. and among the girls nine per cent., suffer from more or less serious defects of the visual organs. It is noteworthy that the proportion of scholars with visual defects was much more marked in the poorer districts than in districts of a better class, and it is greatly influenced for the worse by the presence of children of foreign parentage. It is estimated that two years will be required to complete the examination of all the children, who number about 60,000. This result amply justifies the necessity for systematic examination of new scholars, since much of the labor bestowed on the defective children is thrown away in consequence of their physical inability to derive the benefit thereof.

VENEREAL DISEASES IN RELATION TO LIFE INSURANCE.

As a recent meeting of the Vienna insurance doctors, Dr. Löw read a paper on this subject. He said that it is generally held that an attack of syphilis radically depreciates the "life value" of the victim, and from a sickness point of view it may fairly be assumed that for some years after an attack, the liability to disabling sickness is tangibly enhanced. The view is equally accepted that an attack of gonorrhea entails no serious consequences once it has been recovered from, and it is not even customary to ask candidates for sickness or life insurance whether or not they have ever suffered therefrom. If, however, any practitioner asks himself which disease in his experience has most manifestly contributed to cause invalidity and premature death he will not improbably be disposed to state that the ultimate results of gonorrhea are at least as disastrous as those of syphilis. For one case of locomotor ataxia or other nervous disease recognized to be dependent on syphilis there are probably many of enlarged prostate, vesical and renal disease directly due to the presence of an urethral stricture or to past inritation of the prostate. Then, too, there is such a thing as gonorrheal rheumatism, which is far more frequent than is suspected, in spite of the maxim that inflammation of a single large joint, apart from trauma, is generally of gonorrheal origin. There is, of course, the fundamental difference, that while in gonorrhea any subsequent mischief is the direct consequence of a lesion ascertainable on examination, that associated with syphilis is more occult, and may give no indication of its existence until the symptoms of the impending disease present themselves. The question is one of considerable interest from the insurance examiners point of view, and it can only be cleared up by careful study.

NEW REGULATIONS FOR FEMALE TRAVELERS IN HUNGARY.

The minister of the Hungarian railways has issued new regulations to the railway guards wherein they are earnestly admonished to segregate strictly women passengers traveling without escort. That this has become increasingly necessary, was emphasized by a sad incident which occurred a few days ago. A girl of sixteen (travelling in the third class), through lack of room in the female department of the car, entered a smoking car. The men therein carried on during the journey such a vulgar and disgusting discourse that the girl, when leaving the car, fell down from nervous prostration as the consequence of the filthy conversation she had been compelled to listen to. This new decree, that girls without escort must not travel in railway cars, except in reserved compartments, has been received with general favor

THE CORRODING EFFECT OF ALCOHOL ON INSTRUMENTS.

Surgeons who use alcohol for the sterilization of instruments will doubtless be interested in some experiments, which have recently been made by Dr. Jacobovici, professor of surgery at the University of Bucharest, with the object of discovering the effect of absolute alcohol on metals. Dr. Jacobovici in his experiments used ninety-five per cent. alcohol which left no residue on evaporation. The metals—copper, iron, tin, lead, zinc and galvanized iron—were corked up with alcohol in glass flasks and kept at ordinary temperatures for six months. The copper was entirely free from corrosion but in all the other flasks there was a deposit on the bottom and the metal was covered with a similar deposit. In the case of tin, lead, zinc and galvanized iron the deposit was white; that from the iron was red, resembling iron rust. All of the liquids, except that in which the lead had been placed, filtered clear; the latter retained a milky appearance after repeated filterings through double filters. The clear filtrates from iron, lead, zinc and galvanized iron gave much residue on evaporation, while the residue from tin was hardly appreciable. In the former group it is clear that not only had the metal been oxidized, but a considerable quantity had entered into the solution. Dr. Jacobovici's experiments have had quite similar results to that of Dr. Malmejac carried out about a quarter of a century ago.

THE MEDICAL EXAMINATION OF SCHOOL CHILDREN.

The Board of Sanitation of the City of Vienna has decided to ask the school medical officers of the city to undertake a general medical examination of Vienna school children every two months, and to record the condition of the mouth and teeth on a special sanitary card, as is done in Paris. When necessary, the children will be sent to dental surgeries selected for the purpose by the authorities.

THE UNIMPORTANCE OF A NEGATIVE WASSERMANN REACTION.

Dr. Konrad, lecturer on venereal diseases in Breslau, Germany, says in an article on the subject of a negative Wassermann that most unfortunate consequences attend the practice of attaching too much importance to a negative reaction.

GENEVA LETTER

(*From our own correspondent*)

GENEVA, *March 20, 1923.*

TREATMENT OF LOCOMOTOR ATAXIA.

(*Concluded from page* 245)

One cubic centimetre of solution should contain one centigram of the drug, this being the dose. The treatment is generally well tolerated. If by chance it produces some intestinal disturbance, such as pain in the transverve colon or diarrhea, paregoric or tincture of opium will suffice to control them, if they are not very great. If they persist, the treatment must be given up and commenced again a few days later.

A series of fifteen injections should be given four times a year and twice yearly should be reinforced by a series of arsenical injections, to which reference will be made. The cyanide injections are unquestionably potent and the reason why this treatment is not more general is because it offers certain technical dangers when the procedure is not carried out with exactitude. When from unskilfulness the mercurial salt is injected outside the vein fearful pain ensues with inflammatory swelling which soon becomes hard and extends over considerable area. The patient's general health is affected, even with quite an elevation of the temperature. In most cases sloughing occurs which takes quite a long time to cure, and when recovery has taken place more or less induration *en masse* results with occlusion of the veins, whose permeability is the patient's salvation.

Besides this serious accident there are minor ones which are equally very serious. If the solution is simply injected alongside the vein in a minute quantity pain ensues, with inflammatory swelling and a nodule which will occlude the vessel. On the other hand, if the injection is pushed into the midst of the walls of the vein a nodosity will occur which obliterates the lumen. If the intravenous injection is not given adroitly, if the needle is thrust several times into the vein, the pain caused will discourage the patient and the changes arising in the walls of the vessel from the numerous punctures will result in small cicatrices so that after a time the vein becomes occluded to such an extent that it becomes useless for the procedure. Therefore, the technic must be acquired under the direction of men versed in it and as this means practical work in a clinic no mention need be made of it here.

But I would say a word as to the treatment of the accidents mentioned above, should they arise in the treatment of locomotor ataxia. First be it said that the injection should be given slowly, because some few patients will be distressed if the injection is introduced suddenly. A kind of dyspnea results, with paleness, due to the arrival *en masse* of cyanide of mercury in the bulbar region. When all the solution has been injected it is well to aspirate a little blood into the syringe and reinject it. This little maneuvre rinses the needle of all trace of the mercury so that none is left to escape into the tissues when the needle is withdrawn, which othrwise might give rise to accidents of mild degree.

If a little of the solution should be injected along the outside of the vein the following measures must be resorted to without delay. Fifty cubic centimetres of sterile water should invariably be ready at hand and to this one centigram of cocaine hydrochlorate is added. A needle is then pushed in under the point at which the mercury solution has entered the tissues and twenty c. c. of the cocaine solution injected. The needle is then withdrawn a little and ten c. c. of the solution injected at the spot where the mercury has escaped in the tissues and finally the needle is still further withdrawn and twenty c. c. more of the cocaine solution is injected at the point under the skin at which the mercury solution was given. By this means an extreme dilution of the mercury solution is obtained so that it no longer has a caustic action, while at the same time a layer of water is injected above and below the point of injection of the mercury solution, which protects the tissue from the action of the latter.

On the other hand, as the solution contains cocaine the pain is abolished. It is well to employ a needle, such as that used for intramuscular injections for making the "three layer" injections, so that it can be pushed in in various directions like the spokes of a wheel in each layer in order to spread the solution. A hot moist dressing is then applied. These dilute cocaine injections should be renewed ten hours later and then once a day for six days. Some induration will occur but it does not slough and by massage the tissues may acquire their former softness.

It is well to recall that when the mercury solution is injected into the lumen of the vein the patient occasionally experiences rather sharp pain lasting a couple of hours, following the course of the vessel up to the clavicle. This pain is endovenous and Chauvet regards it as due to irritation of the sympathetic nerve filaments and not to that of the venous endothelium. As it is observed on certain days and not on others, this observer is inclined to suspect that the composition of the blood varies, at times mixing well with the mercury solution, at others not, thus explaining the pain when this is the case.

Injections of novoarsenobenzol should be given once a week. Remarkable results are obtained in tabetics, as well as in general paresis, but large doses are to be avoided, small ones are better and given over a longer period of time. Begin with ten centigrams and if the first injection is well tolerated repeat this dose at the second. The four following injections are fifteen centigrams each, the next two twenty centigrams each, and if all goes well, the last doses may be thirty centigrams each. Ten injections are given in all. The arsenic injections must always be given at the patient's house and he should always be fasting and in bed. Should nitritoid accidents supervene they are to be dealt with by intramuscular injections of adrenaline hydrochlor.

Such briefly, is the treatment most generally adopted in France and Switzerland for incipient tabes, but when intravenous injections cannot be given because of the small calibre of the veins, or on account of an excessive amount of subcutaneous fat, intramuscular injections may be used. These consist of one centigram of oxycyanide of mercury dissolved in two cubic centigrams of Locke's solution to which one centigram of stovaine has been added.

Radiotherapy for radicular pain is under study and at the present writing I think it is fair to assume that the results are on the whole encouraging.

Book Reviews

GONORRHEA

Die Gonorrhoe des Mannes und ihre Komplikationen. By Geh. San-Rat Prof. Dr. Hans Wossidlo. Third Revised Edition, by Dr. Ehrich Wossidlo. Leipzig: Verlag von Georg Thieme, 1923.

This third edition of the well known work by the late Hans Wossidlo, and which the younger Wossidlo dedicates to the memory of the elder, does not differ materially from its predecessors. Ehrich Wossidlo has revised the work and has added new chapters on vaccine therapy and diathermy, but the work still remains practically the same.

One does not find anything new or startling in this volume; it even appears that some of the smaller and less pretentious volumes on gonorrhea in the male which have come out of Germany recently have been more modern in scope and outlook, particularly in the matter of diagnosis and the employment of diagnostic aids. The new chapters on diathermy and vaccine therapy cover the usual ground and constitute a safe guide for the treatment of gonococcal complications.

CYSTOSCOPY

Handbuch der Cystoskopie. By Dr. Leopold Casper. Fifth Edition, with 170 Illustrations and Twelve Plates in four colors. Leipzig: Georg Thieme, 1923.

The fourth edition of this classic work by Casper which was reviewed in these columns about a year ago, has been so rapidly exhausted that a fifth printing has been found necessary. Casper has taken advantage of this necessity and has revised in some measure certain parts of the work, bringing it up to date. Nine illustrations have been added in the text, but the colored plates both as to character and number remain the same as in the last edition. Special emphasis is attached to pyelography, especially in children, and to radiography of the urinary tract. The student and practitioner of cystoscopy will do well to have this volume and master its teachings.

METHODS OF BACTERIOLOGICAL EXAMINATION

Praktikum der klinischen, chemischen, mikroskopischen und bakteriologischen Untersuchungsmethoden. Von San.-Rat Dr. M. Klopstock und Dr. A. Kowarsky. Berlin und Wien: Urban & Schwarzenberg, 1923.

In this, the seventh edition of this book, the authors have replaced the tests that require expensive or large amounts of costly reagents by those that are simpler and cheaper, but this replacement was always made with an eye toward accuracy and reliability. A greater importance is given to the subject of micromethods. Some of the more recent reactions that have received recognition are also included, such as the gold sol and mastic reaction, the determination of the bilirubin content of the blood, of the rapidity of sedimentation of the erythrocytes, etc. Of the more recent serological tests, the clouding reactions of Dold and Meinicke are described. The various chapters deal with the following subjects: bacteriological examination of the secretions and deposits of the mouth and pharynx, of the nasal and the conjunctival secretions, the sputum, gastric contents, feces, urine, the urethroprostatic secretion, the blood, punctates and the skin. A separate chapter is devoted to the usual bacteriological methods of examination, the staining formulæ used and the nutrient media. This book is of assistance to the general practitioner who wants to brush up on clinical pathology.

ANEMIA.

Les Anémies. By Dr. Leon Tixier. Paris: Ernest Flammarion, 1923.

This book is the fruit of the author's twenty years' experience with diseases of the blood. The nature and the causes of the different types of anemia are discussed. Special attention is devoted to the anemias of infancy. In the section on anemias of adults the causes of secondary anemia are well presented. Throughout the book the author gives evidence of his thorough knowledge of the literature. It is doubly unfortunate, therefore, that he has completely omitted a bibliography. One third of the monograph is devoted to a discussion of the treatment of the anemias. This section might well have been abbreviated. Many therapeutic agents of decidedly questionable value, such as, for instance, the socalled hemopoietic serum, or thorium-x hardly warrant such lengthy discussion in an elementary monograph.

TONSILLECTOMY

Tonsillectomy by Means of the Alveolar Eminence of the Mandible and a Guillotine. With a Review of the Collateral Issues. By Greenfield Sluder, M. D. St. Louis: C. V. Mosby Company, 1923.

While we are seemingly passing the peak of tonsil slaughter and are gradually but surely descending to the level of commonsense and definite surgical indications for removal of the tonsils, there is still a great deal of haziness and uncertainty prevailing in the minds of the operators both as to indications for and the methods of removing tonsils. We therefore welcome the appearance of a book from the pen of a worker whose experience and erudition have greatly helped in establishing tonsillectomy on a more or less secure surgical basis. The subject proper is preceded by a general survey of the embryology, physiology and general pathology of the tonsils, a thorough familiarity with which should be a prerequisite for any method of tonsillectomy. In the description of the operation which occupies half of the volume we notice, among other things, that the author is strongly opposed to the use of morphine before anesthesia, as it is prone to abolish the cough reflex; this is somewhat at variance with the practice of other equally prominent laryngologists. The author's favorite anesthetic, and with good reason, is nitrous oxide gas, whose properties lend themselves particularly to his method of operation. While naturally a staunch advocate of his own method, he is careful to warn those who have acquired satisfactory skill in other methods not to abandon them in favor of a new one.

The perusal of this book will surely put the reader in possession of almost everything worth knowing at the present time regarding the tonsil and its removal, and we heartily recommend it as a valuable addition to every laryngologist's library.

TUBERCULOSIS

A Simple Treatment for Tuberculosis. By Owen F. Paget, M.D. With introduction by J. George Adami, M.D., F.R.S., and Prefatory Remarks by W. P. Birmingham, B. A., M.D. New York: William Wood & Company, 1923.

Dr. Paget's treatment consists of the nasal inhalation of powdered tuberculin B. E. in doses of one six thousandth mgm. to one fortieth mgm. His thesis is that the nasal passages, particularly in the region of the ethmoidal cells, have not alone a local immunity to tuberculosis and to other infections but through their epithelium the power of provoking a general immunity to the invading organism. As a natural corollary to his theory he emphasizes the great importance of nasal breathing and goes so far as to say "The baby who eats soft foods develops weak jaws and inefficient nose, and dies of tuberculosis."

The book, although interesting, is not convincing. One rather agrees with the opinion of a trained expert in tuberculosis under whose supervision Dr. Paget treated a series of cases in the Canadian army. "He was convinced of Dr. Owen Paget's complete sincerity, but could not see the improvement in the cases that was manifest to Paget, and as a skilled diagnostician he regarded Paget's diagnostic methods as rough and ready." It is unfortunate that the book may give the rhinologists another excuse for unwarranted nasal operations.

SURGERY

Mistakes and Accidents of Surgery. By Harold Burrows. New York: William Wood & Co., 1922.

The title of this book is unusual and the reviewer commends the author for his honesty in attacking the problem. It would seem that there would be a decided call for a book of this type with, however, a much more thorough and complete study of the question. The author takes up the various anteoperative errors, then errors that may occur during the operative procedure and finally the postoperative complications. He brings in numerous case reports which add to the interest. One feels, however, that he has not taken up as thoroughly as he might the various diseases that he has discussed. For instance, there is no mention of lung abscess as a sequel to tonsillectomy.

There is no mention in his discussion of gallstones as the anteoperative treatment for lessening the coagulation time in cases of jaundice. In his discussion of diseases of the kidney, cystoscopy for the study of kidney function is not mentioned, nor does he say anything in regard to estimation of urea nitrogen and creatinin in the blood as a means of prognosis in prostatectomy. American urologists have made a thorough study of this subject and by the data derived therefrom can decide whether a two stage operation with primary drainage of the bladder either by a retention catheter or suprapubic cystoscopy is indicated. His article on hernia is excellent. He gives very good and timely advice about empyema—particularly does he show the inadvisability of attempting the most dependent drainage. Too many surgeons have found to their sorrow that after dependent drainage the diaphragm raises and obliterates the costophrenic angle, thereby producing an elongated sinus with insufficient drainage. One feels on reading the chapter on intestinal obstruction that not enough importance is placed on the early operation, speed and gentleness of handling the tissues and the type of anesthesia to be used.

SURGICAL CLINICS

Surgical Clinics of North America. Volume 3, Number 3, San Francisco Number. Published Bimonthly. Philadelphia and London: W. B. Saunders Co., 1923.

Twenty-six surgeons contribute twenty-four clinics to this interesting number of the *Surgical Clinics.* Outstanding features of the number are the clinics by Frank Hinman, on Prostatectomy as a Standardized Operation, Surgical Treatment of Burn Scars, by G. W. Pierce, and a Case of Early Benign Adenoma of the Appendix, by Emge and Cowan. The illustrations are unusually clear and distinctly valuable in conjunction with the text matter. The printing and paper are all that could be desired.

X RAYS

X Rays. By G. W. C. Kaye. Fourth Edition. With Illustrations. London: Longmans, Green & Co., 1923.

This is the fourth edition of a book which is absolutely authoritative. Paraphrasing the heading of a famous New York newspaper: If you see it in Kaye it's so. While giving the basic principles of radiography even to such modern topics as the use of the Bucky diaphragm it does not give directions for radiographing different parts of the body. It gives only a few radiographs, not being intended as a guide to x ray diagnosis. Neither does it discuss the diseases amenable to x ray treatment or its application to each.

A most interesting interview in 1896 between McKenzie Davidson and Röntgen is recorded in which the latter described his discovery of the x ray. He was looking for invisible radiations from a vacuum tube actuated by a high voltage current and had the tube completely covered with black paper. To make sure that no ray of visible light escaped from the tube he darkened the room and saw that a barium platinocyanide screen at a distance of some metres was brightly illuminated by rays which had evidently passed through the black paper. Asked what he thought when he saw this, he answered, "I did not think, I investigated."

During the war the x ray was employed after extensive plastic operations upon the face to prevent induration and contracture of the flaps. Sheet lead is the best means of protection from x ray injuries and only one ten thousandth of the very hard x rays generated by two hundred thousand volts passes through one eighth inch of lead.

Tables are given showing the voltage indicated by parallel spark gaps. Needle points a certain distance apart, permit sparking with a much lower voltage than polished spheres and the latter to be most reliable should have a diameter fully half the spark length to be measured. This prevents the electric leakage or corona discharge. Ionization of the air is produced by the x ray independent of its quality or hardness and affords a reliable measure of its quality. But the currents permitted to flow by air so ionized are only of the order of one billionth of a milliampere so that a milliamperemeter is not commonly used. Instead we watch the rate of discharge of an electroscope charged with static electricity and connected with an ionization chamber exposed to the x ray. X rays passing through air supersaturated with watery vapor produce ions upon which particles of water condense and an instantaneous photograph by a brilliant light shows a maze of these particles in rapid motion. This is one of the most interesting pictures in the book.

The author regards x rays and all other electromagnetic waves such as ordinary light and the Hertzian waves of radiotelegraphy as the "riddle of modern physics." A useful conception is that an x ray is a separate entity like an individual bullet from a battery of machine guns which might be fired almost simultaneously in every direction. Each x ray goes in a narrow path which does not expand and become diffused and weakened by distance. The combined effect is reduced in proportion to the square of the distance because a given number of x rays are distributed over a greater surface. An x ray according to this conception is not like a chain reaching from the source to the point where it may terminate as at a piece of lead but it may be likened to a short length of chain propelled from a cannon and not connected with anything in front or behind itself. This simile is the reviewer's. According to this conception also an end view of a beam of x ray would be a field of luminous points not of uniform illumination. A modern theory of ordinary light is also of this nature.

In making a radiograph, a photographic plate or film records only about one per cent. of the energy of the x ray. The film is much more sensitive to ordinary light and a fluorescent screen in contact with the film converts so much x ray energy into light that the effect upon the film is multiplied. This is the principle of the intensifying screen. The Impex x ray plates have a fluorescent coating which produces the same effect as a separate screen and is washed off before development. The radiographic effect of hard x rays, according to Kaye, may be multiplied thirty times.

Especially sensitive plates, he says, reduce the proportionate effect of secondary rays which arise from the tissues. An interesting application of the x ray is to examine golf balls with reference to the dense solid or liquid core being properly centred, if not, it would fly and roll irregularly. Another is to examine aeroplane parts for defects such as a concealed part split by a screw. Finger prints are very simply made radiographically after rubbing the fingers with red lead. An x ray, whatever its nature may be considered, sets free an electron when the x ray collides with an atom. It is in this way that ionization takes place. But this happens to only a small percentage of the x rays passing through a given medium.

The work gives a most complete, accurate and interesting view of the discovery, production, nature and uses of the x ray.

ELEMENTS OF PSYCHOLOGY

Elements of Human Psychology. By Howard C. Warren. New York: Houghton Mifflin Company, 1922.

The style of this book fits it as a useful reference or textbook for a complete survey of the elements of psychology, the various forms and methods of mental action and their close relation to forms and mechanisms of nervous activity. Only for the most part the author remains upon the surface of things. One can hardly escape in these days some reference to that greater part of mental activity, the dynamic working below the surface. But the references to it are so inadequate as to be actually misleading. For it not only tacitly denies much that goes on there but gives a false conception as to how psychic ends can be attained or difficulties be avoided or corrected. If this is the form of psychology that conceives of anything below the surface as a relatively negligible "subconscious" then let us have a psychology that boldly accepts a profound "unconscious" and all that that might contain.

SANITY IN SEX

Sanity in Sex. By William J. Fielding. New York: Dodd, Mead & Co., 1922.

There is much good material in Fielding's book but so eclectic an attitude is maintained that incompatibles are frequently mixed into a self vitiative dose making its value questionable.

Practically the identical material has been handled in the same way by Pierce. All that one can do in criticizing this book would be to repeat what has been said about Pierce's book. There is little choice between them. More fundamental books have been written on these subjects.

HOW TO WRITE A DETECTIVE STORY

The Vengeance of the Ivory Skull. By Marion Harvey. New York: Edward J. Clode, 1923.

At least five deaths to satisfy the primitive urge of number symbolism. A chain of mystery stretching over three continents and an ancient legend to fall back upon as the final hill in the unravelling. This gives you the ingredients of a most absorbing detective story, free moreover of much of the romantic slush that hampers many a good tale. For no dashing young discoverer marries the misjudged heroine. Instead it is truly a tale of sombre vengeance relentlessly pursued. The touchy, elderly archeologist who is unwillingly drawn into the coils of circumstance furnishes the comic relief and a suitable scientific coloring.

The Sinister Mark. By Lee Thayer. New York: Doubleday Page & Co., 1923.

Light literature for sultry weather! What could be more thoughtful than this latest offering of Doubleday Page & Co. It is the kind of story one reads at a sitting prolonging the evening far into the night if need be. It is not thrilling; its dénouement is not blindingly unexpected. It is just a good old fashioned story of the thorny path true love must tread to scale the glass mountain of the fairy tale. And in this case the glass mountain consists of about every known force of modern obstacle with particular emphasis on the medical side.

AXIOMS AND APHORISMS

Medical Axioms, Aphorisms and Clinical Memoranda. By James Alexander Lindsay, M.A., M.D., F.R.C.P. London: H. K. Lewis & Co., 1923.

The preface of this little book states that "many of the following medical axioms, aphorisms and clinical memoranda have been familiar to several generations of the Belfast Medical School. They are now published in response to many requests, in the hope that they may prove of usefulness to a wider circle." There is certainly much good material in the book, but, since authorities are quoted by no means frequently except in the section devoted to philosophical epigrams, one wonders just why the book is of any great value, except as something of a curiosity in that it is a collection of quotations that may have sometimes a very slight connection with medicine. One gathers that British medical men must have more time for "browsing" than doctors in this country.

Medicoliterary Notes.

Some enterprising psychoanalyst should analyze Algernon Blackwood's *Jimbo: A Fantasy*. The fact that the book is by no means a recent one would make such a study all the more interesting, since it was written long before the layman had any general knowledge of the science of mental analysis. It would be as valuable a contribution to child psychology as Freud's *Study of Gradiva* is to the psychology of adolescence.

* * *

The American Child Health Association has recently issued its fourth annual tabulation of infant mortality statistics from cities of over ten thousand population. The report covers 635 cities, or 97.8 per cent. of the total population.

* * *

A recent book on sex, which is certainly of controversial interest at least, is *The Dominant Sex*, by Mathilde and Mathias Vaerting, a translation of which from the original German has been published by Doran. The authors' point of view is that personal characteristics, instead of being socalled masculine and feminine, are really only the results of domination or subordination of one sex by the other. Illustrations are given from the ethnological histories of countries where sexual supremacy has differed from that of the present time in which men dominate women. The book concludes with a plea for sex equality.

* * *

Probably few people know that the United Fruit Company, whose general offices are in Boston, maintains in many portions of tropical America an elaborate medical department for the care, treatment and education in health matters of its employees. This includes nine hospitals, exclusive of dispensaries, and a personnel of nearly six hundred, including physicians, registered nurses and other trained attendants.

* * *

A medical book which is entertaining as well as instructive is *Cures* by Dr. James J. Walsh, recently published by Appleton. It is a record and history of the many panaceas in which mankind has believed, suffered from and been benefited by, from the earliest times to the day of Coué and the psychoanalyst.

* * *

A million dollar hospital for stage folk will be constructed in New York in the near future, according to plans being completed by the recently organized New York Theatrical Hospital Association, of whose executive committee Dr. McCall Anderson is chairman. The building will probably be eight stories high and have a capacity of one hundred beds. Final plans, it is reported, will be announced early in the autumn.

* * *

The *World's Work* for August contains an article by Ernest H. Baynes entitled Vivisection and Animal Welfare, in which the annual saving from suffering and death of millions of animals through humane and scientific animal research and experimentation is explained and described. Floyd W. Parsons has in the same number an article on Ventilation for Health and Comfort.

* * *

Among other interesting articles in the *Journal of Industrial Hygiene* for June are Atmospheric Particulate Matter: Dust, with a New Apparatus for Its Determination, by Philip Drinker and others; and Prevention of Industrial Lead Poisoning in English Factories, by A. C. Burnham.

* * *

Social Control of the Feebleminded is the title of an excellent new book by Stanley P. Davies, executive secretary of the Committee on Mental Hygiene of the State Charities Aid Association. It is a study of social programs and attitudes in relation to the problems of mental deficiency. Four chief stages of development are reviewed: The ancient and medieval period to the nineteenth century; the period of physiological education, beginning with the first attempt at the scientific treatment of mental defectives and ending with the establishment of the earliest institutions in this country; the "alarmist" period, roughly from 1900 to 1915, when the numerous intensive studies of the subject of feeblemindedness made it a social problem of the first magnitude; and the modern period characterized chiefly by emphasis of extrainstitutional care.

* * *

A study of five thousand vacation camps in this country is being made by the Playground and Recreation Association of America, financed by the Laura Spelman Rockefeller Memorial. The work will include the preparation and publication of a practical summer camp handbook.

* * *

The total number of deaf mutes reported in the United States was 44,885 in 1920, or 425 for each million of general population.

Practical Therapeutics

TREATMENT OF SYPHILIS WITH MASSIVE DOSES OF MERCURY INTRAVENOUSLY

By R. A. Ireland, M. D.,
Charleston, W. Va.

Every physician who treats syphilis desires a much more satisfactory method for exhibiting mercury. Like many other syphilologists I have used the entire gamut of mercury compounds and forms, but the well known advantages and disadvantages inherent in all of them leaves much to be desired in the administration of mercury. Mercury in forms thus far intravenously injected is recognized as being conducive to the quickest results (1) although the dose of mercury thus far given is so small that it is too rapidly eliminated to have a sufficiently profound therapeutic effect and also damage to the vein is by no means infrequent (2).

The intravenous injection of the soluble salts of mercury has always had the drawback of exhibiting too little mercury to receive the full benefit from an intravenous injection. It has always been my conviction that if mercury could be administered intravenously in large enough amounts the treatment of syphilis would be conspicuously advanced. I have been able to substantiate this view and I am detailing below the results obtained through the use of a new mercurial preparation that safely permits of the two essential factors just mentioned, viz., intravenous application and heavy doses.

The medication is called lueside, and is a gray powder composed of chemically pure glucose in which, by some process, metallic mercury has been comminuted. When this powder is dissolved in the proper amount of distilled water (fifty c. c.) a dark gray solution is formed. The color is due to innumerable minute globules of metallic mercury that are suspended in the water. Fear of embolism, however, proved unfounded because mercury being a liquid, the fine globules of this material in the medication seem to pass as freely through the capillaries as water. In administering this metallic mercury intravenously the highly desirable feature of heavy mercury doses with safety is accomplished.

The total amount of the mercury contained in a dose of this preparation is one half gram. I administer two fifths to four fifths of the full dose, or two hundred to four hundred milligrams of mercury every dose, which contrasts strikingly with four or five milligrams of mercury in one twelfth of a grain of bichloride of mercury that is frequently administered intravenously.

Rarely does any symptom of mercurialism appear. Such symptoms usually are only a diarrhea, no kidney damage ever occurring. On the other hand a sustained therapeutic effect is obtained from the large dose of mercury that produces results of a striking nature and confirms the view above stated that the intravenous application of large quantities of mercury is ideal in the treatment of syphilis. Metallic mercury as described here permits of a freedom from toxicity that allows the desired heavy dose without any unpleasant general reactions. In respect to local reactions at the point of the injection no phlebitis or thrombosis of the vein has ever occurred, the metallic mercury being noncorrosive.

In respect to the time for the administration of these massive doses of mercury, I have used it principally in secondary and tertiary syphilis. The massive doses of mercury seem to saturate the lymphatic stream and tissues with mercury.

The following is a series of syphilitic cases which received treatment consisting of heavy doses of mercury intravenously administered.

Case I.—R. S., a while girl, seventeen years old, had just finished taking ten doses of neoarsphenamine and nine doses of arsphenamine and her Wassermann was still four plus. When she was brought to my clinic I determined to try a radical departure from the orthodox line of treatment, and gave her intravenously every seven days 300 milligrams of mercury in the form of lueside. I continued this for eleven doses and now four months after the last dose her blood is reported negative and she seems to be well.

Case II.—C. T., a white girl, twenty years old, had received sixteen doses that she thinks were about equally divided between neoarsphenamine and arsphenamine, and some mercury. Two months later mucous patches developed and she had headaches. Her Wassermann was four plus. I gave her six doses of 300 milligrams of mercury intravenously and interspersed these with three doses of arsphenamine. Now, three months after finishing treatment, she is well and has a negative Wassermann.

Case III.—L. F. P., a male negro, aged twenty-two, had had thirty-eight doses of arsphenamine and neoarsphenamine and small amounts of mercury over a period of three years. He had improved each period when given continuous treatment for a few weeks, only to relapse after treatment had been suspended for a month or two. His Wassermann was four plus, he had syphilitic ulcers on each leg and at the rectum. He was given three six tenths gram doses of arsphenamine and this followed by ten 350 milligram doses of mercury seven days apart. Now, six months after finishing the mercury treatment, his ulcers are healed, he is able to work, and his Wassermann is negative.

I have used lueside on fifty different patients and have given one hundred and thirty doses without bad effect.[1]

CONCLUSION.

The intravenous application of comminuted metallic mercury affords a marked advance in the treatment of syphilis. Such mercury does not produce any disagreeable reaction of either a general or local nature.

[1] An additional series of cases in which this preparation was used at the Penitentiary Hospital and Dermatological Station at Welfare Island, New York City, will be published in the author's reprints.

THE SALTS OF BISMUTH IN SYPHILIS

By B. Sherwood-Dunn, M. D.,
Nice, France.

Since the discovery by Ehrlich of the remarkable efficacy of arsenic in the treatment of syphilis, this remedy has come into universal employment and salvarsan is probably the preparation most generally used. The numerous accidents, some fatal, that have attended this particular preparation, have given rise to many modifications of it, some of which have survived and found a permanent place in our therapeutics.

At infrequent intervals, however, cases occur that prove refractory to arsenic and a question that is interesting many investigators is what remedy can be successfully substituted in their treatment, and among those mentioned bismuth seems to be one of the most favored.

The researches of Robert and Sainton have brought to light the parasitical properties of the salts of bismuth in relation to the protozoa. The study of these salts, in relation to syphilis, made by Balzar in 1889, has been confirmed by the experimental work of Sazerac and Levaditi and clinically by the work of Fournier and Guynot. In accord with a number of other experimenters these authors declare that bismuth should be considered as one of the energetic agents in the treatment of syphilis. Various salts of bismuth, some soluble and others insoluble, have been utilized.

Sazerac and Levaditi in their communication to the Academy of Sciences of Paris concluded by saying that not sufficient time has elapsed to pronounce upon the permanency of the favorable results secured, but that they feel fully authorized to recommend bismuth as a dependable remedy in the treatment of syphilis.

The injection of these salts caused the rapid disappearance of the treponema and the open lesions. The rapidity of this action has been confirmed by Jeanselme, Chevalier and others. Jeanselme by the disappearance of the treponema sixty hours after the first injection and the favorable action of this agent has been confirmed at all stages of the disease.

Smilyanitch reports a case in the Spillman Clinic, in Nancy, in which the patient suffered a severe stomatitis following injections of grey oil, accompanied by a general exfoliant erythroderma following the third injection of novarsenobenzol. With this evidence of intolerance for both arsenic and mercury the patient was treated by injections of bismuth. The Bordet-Wassermann reaction was positive and became negative after ten injections of tartrobismuth of sodium and potassium, receiving in all a total of two grams. This treatment was well supported with no disagreeable manifestations whatsoever.

Smilyanitch relates the history of another patient with secondary syphilis who presented the same phenomena following three injections of mercury; the patient showed all the signs of serious intoxication, including an intense general exfoliant erythroderma. The treatment was changed at once to injections of bismuth. Ten injections of tartrobismuth of sodium and potassium 0.20 gr. of salt were injected, making a total dose of two grams. The Bordet-Wassermann reaction showed a feeble positive reaction at the beginning of the treatment and was found negative at the close. Nicolas reports a case in which there was a relapse in a short period after each treatment with novarsenobenzol, but permanent good results were secured with the salts of bismuth. He also states that he caused the rapid disappearance of accidents by the use of bismuth in a patient who was intolerant of arsenic and in whom mercury seemed to have no effect.

Guilbert reports a case in which the patient was intolerant of arsenic and mercury administered upon the appearance of the primary chancre. The presence of the treponema was verified by the microscope. The patient was treated by simultaneous intravenous injections of arsenobenzol and intramuscular injections of grey oil. He received a total of 6.25 gr. of arsenobenzol. During the entire duration of the treatment, instead of an amelioration, there was a progressive aggravation and extension of the primary chancre. In consequence, he was submitted to treatment by hot air, hot baths, etc., without success. Finally without any great enthusiasm he administered injections of tartrobismuth of sodium and potassium. After six injections there appeared a decided amelioration and cicatrization was complete after the eighth injection.

Fixier has reported an extremely interesting case of hereditary syphilis in a child of twelve years, who during a period of four years showed not the slightest favorable results from the administration of arsenic, mercury and iodide, but who responded immediately and in a most favorable manner to the administration of bismuth.

Azotolay has published a case of precocious malignant syphilis in which thirty-six injections of 0.02 gr. of benzoate of mercury were administered without the slightest benefit and, on the contrary, presented ulcers three months after the commencement of the treatment. A decided abatement of all the symptoms with complete cicatrization of the ulcers was secured at the end of twenty-eight days after twelve injections of the iodide of bismuth and quinine.

Leri, French and Wissmann-Netter have published an extremely interesting case of a patient, twenty-eight years of age, who fifteen days after the appearance of the chancre presented a general pustulous eruption profoundly ulcerous and with crusts, who in addition to high fever was in a state of general anemia (2,300,000 red corpuscles) and as is general in precocious malignant syphilis, no involvement of the mucosa, and no general adenopathy. The Bordet-Wassermann reaction was already positive. With difficulty a few rare treponemas were found in the ulcers. After six injections of 0.20 gr. of quinobismuth, two a week, well supported, the ulcers became cicatrized, the fever disappeared, and the red blood corpuscles were increased to normal, although the polynuclear leucocytosis persisted.

A peculiar accident appeared in this case, for as the ulcers cicatrized a lesion appeared upon the tongue, which gave rise to the thought that it might be due to intoxication from the bismuth, but as the results in every other respect were so favorable the treatment was continued and this lesion disappeared, showing that it could not be imputed to the bismuth.

The nitritoid crisis never follows the administration of bismuth.

There are two principal forms of bismuth in use, the tartrobismuth of sodium and potassium (soluble), prepared in an aqueous solution and also suspended in oil. The sterile aqueous solution is stabilized and neutralized and put up in ampoules representing one c. c., which contains 0.10 gr. of the bismuth salt, corresponding to 0.032 or 0.035 gr. of the metal. The solution is rendered sterile without the addition of any form of antiseptic or anesthetic. In general it is well retained, the injections are made fairly deep in the classical region of the gluteus muscle. A cure requires the injection of from fifteen to twenty ampoules, one ampoule every two days or two ampoules may be injected at a time, at intervals of four days. At the close of the series of fifteen or twenty ampoules, the patient is given a rest for a month, when the treatment can be repeated, if the Bordet-Wassermann reaction indicates that it is necessary.

The tartrobismuth of sodium and potassium, although perfectly soluble in water, is not soluble when suspended in oil, except as it comes into contact with the fluids of the organism, which render the combination soluble, but it is absorbed much more slowly than when suspended in water, and there are advanced cases where this retarded solubility is desirable.

The second form of the remedy is insoluble and consists of the double iodide of quinine and bismuth, containing 19.02 or 19.05 gr. of metallic bismuth for every 100 grams. It is prepared in ampoules containing three c. c. and sterilized by heat; each c. c. represents ten centigrams of the product, or 0.0192 or 0.0195 gr. of the metal.

The intramuscular injections are made the same as for the aqueous solution. As the consistence of the suspension is fairly heavy, rendering its flow somewhat slow, it is necessary to employ a rather heavy needle of from eight to ten millimetres, and it is well to employ one needle for aspiration and a second needle for the injection. The treatment consists of twelve ampoules, one used at a time, at intervals of three or four days, which can be repeated, if the Bordet-Wassermann reaction is not completely negative after a rest of from four to six weeks.

A recent published work by Professor Ehlers, of Copenhagen, gives many interesting details of favorable results with this remedy (1).

The inconvenience attached to this remedy is the local discomfort of the injection, which is rarely of any great consequence if the injections are correctly given, and the patient must be watched for evidence of intolerance, usually shown in a more or less marked degree of stomatitis, which is readily controlled if proper precautions are taken at its inception.

I do not think that any investigators believe that bismuth is destined to be a substitute for arsenic in the treatment of syphilis, but they do assert that it plays an important rôle in cases that are resistant to arsenic and mercury.

To those of my readers who care to investigate the various claims put forward for bismuth in the treatment of syphilis, I have prepared a bibliography which covers the subject in all of its aspects. This bibliography will appear in my reprints.

UNTOWARD RESULTS OF INTRAVENOUS INJECTION OF SODIUM IODIDE

By L. Isacson, M. D.,
Sioux City, Ia.

At present, the method of applying medication by the intravenous route is greatly in vogue in the profession; rheumatic conditions, complications of gonorrhea, and all kinds of chronic ailments have been subjected to intravenous injections of foreign proteins, vaccines, and all the chemical agents of our pharmacopœia. The commercial firms putting up these preparations are constantly advertising the splendid results of some workers, while unfavorable or untoward effects are never mentioned.

I wish to report a case of gonorrheal epididymitis, which has been under my care for the past six weeks. Impressed especially by the article of A. Ravich in the New York Medical Journal of May 3, 1923, I employed the sodium iodide treatment.

Case.—C. G. came for treatment on March 1, 1922, with a chronic anteroposterior urethritis, prostatitis, and right epididymitis. The swelling of the epididymis had been present for ten days; there was extreme pain, the temperature being 100° F. Fifteen grains of sodium iodide were injected intravenously, a comparatively small dose, the average amount recommended by Ravich and others being thirty grains. The following morning I was called to the patient, who was confined to his bed, presenting a striking appearance: the upper left eyelid was markedly swollen, together with enlargement of the salivary glands; the patient experienced a great deal of difficulty in opening his mouth, owing to extreme pain. On both hands and forearms there was an extensive erythematous, papular dermatitis, with subjective symptoms of itching and burning; later, some serous exudation developed on the left forearm. The patient complained of violent headache, nausea, chills, vomiting; he was confined to his bed for three days, until all symptoms subsided.

The preparation used was made by a well known drug firm, was taken directly from the container and injected with all aseptic precautions with the Luer syringe.

I believe that all of the symptoms in this case were the result of the mode of administration, and were not due to any idiosyncrasy on the part of the patient, as prior to injection tincture of iodine was applied to his skin and no reaction observed. Subsequently, we gave the patient two grams of sodium iodide by mouth, with no untoward effects. While this is an isolated case, and no definite conclusions can be arrived at, I feel that this experience is enough to warrant my making the statement that a halt should be called upon promiscuous intravenous therapy.

Cysts of the Epididymis.—R. Ogier Ward (*Lancet,* October 14, 1922) reports that cystic degeneration of the epididymis is a common condition. Its pathology is uncertain. It is a disease of maturity and often affects both sides. If tapping fails to give relief for more than inconveniently short periods, excision of the cyst, or perhaps of the whole epididymis, is necessary, taking care that the vascular supply of the testis is not compromised.

Proceedings of Societies

NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENITOURINARY SURGERY.

Meeting Held on May 17, 1922

DR. ABRAHAM HYMAN in the Chair.

Presentation of Patients, Case Reports, Specimens, New Instruments.—Dr. VICTOR C. PEDERSEN opened the scientific session with two case reports, the first, an unusual one of stone in the bladder of a boy. The outstanding feature of this case was that the bladder wall was found to be at least three eighths of an inch thick. A suprapubic cystotomy was done, and there were indications that the patient's convalescence might be long and troublesome, including a pericystitis followed by a longstanding sinus. But neither of these conditions appeared, and the wound healed with comparative rapidity. During his stay in hospital, the bladder capacity of the patient changed from about one and a half to eleven ounces. There was a relapse of cystitis, but a röntgenograph taken two weeks later showed all parts negative. Dr. Pedersen's personal opinion was the boy would have more stones rapidly, and that another cytoscopy would have to be made under anesthesia. The only analogous case in Dr. Pedersen's knowledge was that of a Chinese morphine addict, from whose bladder a stone the size of an orange was removed.

The second case presented by Dr. Pedersen, with specimen, was that of the removal of the portion of vas and ampulla during prostatectomy. Dr. Pedersen stated that it was the only accident of the kind he had ever had, and that he was presenting it because of its curious results. In performing a suprapubic operation, it was found that the middle lobe was adherent and definitely hard upon dissection. In trying to get out two small nodules which seemed to be holding it, a piece of the vas deferens five or six inches long and the ampulla were removed. Severe complications were expected from this, but seemingly the wound was fairly superficial and not lacerated. Examination of the floor of the bladder at the time of the operation failed to show the opening through which the vas and ampulla had been taken from the usually ragged cavity seen in all prostatectomies. There were no complications, and convalescence went well, except for the return of the cancer signs.

Dr. HOWARD S. JECK next presented a case of tabetic kidneys diagnosed as tuberculous, with autopsy findings.

Dr. W. F. MCKENNA then gave a full history of a case of recurrent renal calculi, with lantern slide demonstrations. The interesting feature of this case was the rapidity of the return of a stone in the right kidney, only about four months having elapsed between the patient's discharge from hospital after a pyelotomy and removal of a stone, and his return, with x ray shadows showing again on the right side.

A discussion by Dr. B. H. CAPLES followed of some new instruments, namely, tunnelled sounds, and a modification of the Maisonneuve urethrotome. In the instruments presented by Dr. Caples were embodied, he stated, the best points of others in use by the profession, and of some which had apparently disappeared from the view of the modern urologist, such as the dilator and catheter devised and used by Sir Henry Thompson in 1852, and later modified by Fessenden Otis. He had added, he said, the accepted sound handle, the groove to facilitate external urethrotomy, had changed the material from silver to steel, and had made it uniform in calibre throughout their entire length. The modification of the Maisonneuve urethrotome was presented because the principle involved was identical, namely, the threading of the staff for its entire length over a whalebone filiform. Dr. Caples closed his subject with a plea for conservatism, patience, and skill in all instrumentation, and that skill be armed with gentleness rather than with fortitude.

Dr. O. S. LOWSLEY spoke of the regional prevalence of urinary calculi, of the possible causes, such as diet, drinking water, infections, urinary obstructions, etc., and of the slight knowledge of postoperative treatment with a view to prevention of recurrence. It was a problem important enough to warrant the most careful research. Dr. MCKENNA said that he considered kidney stones analogous to gallstones, and as the products of infection rather than of diet.

Observations on Intrarenal Pressure in Dogs was the title of the closing paper of the meeting read by invitation by Dr. B. A. THOMAS, of Philadelphia. Dr. J. E. SWEET was a joint author of the paper. They expressed the opinion that, in view of the fatalities and many nonfatal injuries and damage occasioned by pyelography in recent years, this was today one of great importance to the conscientious urologist. A review of the literature of the subject had showed that there seemed to be no uniformity of opinion as to how and why, in the majority of cases, these fatalities and injurious results were produced. Some declared that the various silver compounds employed had caused a complete blocking of the blood vessels; others that a hydronephrotic sac had been ruptured, causing peritonitis; others had attributed death to a reflex inhibition of the heart; others cited anuria, and still others believed that death had been caused by secondary retention of the substances used, due to ureteral obstruction. The one generally accepted opinion and indication seemed to be that as little pressure as possible should be used in making the injection into the kidney. There was, however, no statement as to how excessive pressure acted. Indeed substances absorbed by the kidney seemed to need little or no pressure. Hence arose the question What is the path followed—the secretory system of the kidney, the tubules and glomeruli, or the lymphatics?

The problem of toxicity had been thoroughly studied, with the result that concentrated solutions of the halogen group were being used instead of the more toxic silver colloids. There would seem to be a field for the study of the comparative effect upon the kidney itself of a concentrated crystalloid solution. The authors did not find any discussion of the possible effect of the x ray exposure upon the kidney substance, perhaps rendering it more susceptible to substances to which normally it would not react. Again the question of anuria following pyelography done only on one side might be explained on the basis of a crossed reflex inhibition of function in so far as the healthy or injected kidney was concerned. Definite clinical evidence was quoted in studying the functional sufficiency of renal tuberculosis, with indigocarmen, to substantiate this view.

The writers stated that their early experiments on dogs, directed toward determination of whether or not pressure on the kidney pelvis could produce inhibitory reflexes upon the heart, showed that pressure alone produced not the slightest effect upon the respiration or blood pressure of the etherized dog, so long as a nontoxic solution, such as a normal salt solution, was used. Even a pressure of 400 mm. of mercury could be maintained when the salt solution ran into the venous system of the kidney without the slightest deleterious effect. In investigating this point, the authors found that in pressures of between 150 and 200 mm. of mercury the pelvis of the kidney ruptured, the tear extending directly across the venous system; while further injection into the kidney became nothing more nor less than a direct intravenous infusion. Substituting a toxic solution, such as concentrated sodium citrate, in place of normal saline, the animal died a rapid heart death immediately after the point of pressure was reached at which rupture occurred. The question, therefore, resolved itself, in the belief of the authors, into, What constitutes a harmful pressure? They had come to the conclusion, in conformity with clinical observations, that this point was much lower in the case of diseased kidneys than in normal ones. Indeed, clinically, the disease might be of such a character or extent as to render pyelography prohibitive. The writers stated that they were still working on the problem of how to throw light on the point as to how substances reached the tubules or glomeruli, as a result of absorption from the kidney pelvis, and were of the opinion that the paths differed, perhaps, with the substances or solutions employed.

Dr. Lowsley, in discussing the paper, complimented the authors on their having been able to prove that strong pressure could cause rupture of the kidney pelvis and direct intravenous infusion of the material used. The two important things in pyelography were the choice of the patient and of a nontoxic material. It had been found that sodium iodide was the least toxic. Dr. Lowsley said that, in his opinion, pyelography was not done often enough, but he emphasized the fact that cases must be very carefully selected. It could not be done on the infirm or aged, nor upon those recovering from fever or acute infections. He outlined experiments he had been making upon rabbits in studying kidney conditions.

Dr. Pedersen asked Dr. Thomas if he had investigated the question of nephritis in the dogs he had experimented upon. He said that a friend of his had spent nearly a year experimenting upon dogs with reference to causes of ordinary medical nephritis, when the thought struck him that he had better examine their kidneys. He found that about fifty per cent. of street dogs have this disease. Hence all his work had been useless.

Dr. N. P. Rathbun, Dr. Clarence G. Bandler, and Dr. Abraham Hyman commented most favorably upon Dr. Thomas's interesting paper, and asked a number of questions, which Dr. Thomas answered in his remarks which closed the discussion. He agreed with Dr. Lowsley, that bilateral pyelography was the better. Investigators had found, he said, that the iodides were more irritant than the bromides, therefore sodium bromide had been preferred. It was possible that the iodide might be less toxic than the bromide, but this was not certain. On the one hand was irritation; on the other there might be a toxic effect. Which was preferable, therefore, was difficult to say. It seemed to him and Dr. Sweet that death or damage occurred in one of two ways. There might be a sudden or a slow death. In the event of sudden death, the kidney ruptured and immediate invasion of the bloodvessels by a toxic substance might take place, causing death in a few hours. Cases of slow death might be explained as follows. There might be invasion of the tubules or glomeruli as the result of irritation, which, though it did not cause death, might be the source of sufficient injury to shorten the patient's life, and result in earlier death from low grade chronic nephritic causes than could otherwise have been the case. He had not examined the dogs for nephritis, having been concerned more with the question of pressure and ruptured pelvis than with any other. It was of interest to note that the preponderance of deaths had occurred with collargol and other silver preparations.

Meeting held on October 18, 1922

Dr. Abraham Hyman in the Chair.

Leukoplakia of Bladder.—This report was made by Dr. Julius J. Valentine. He said that the discovery in this case of leukoplakia was incidental; the patient had not presented himself for any urinary disturbance, but for syphilis, and it was the recurrence of the gonorrhea and the persistence of the turbid urine that led to a cystoscopic examination, at which time the lesion was found. As to whether or not the lesion itself was producing the symptoms, he had been in doubt, but the man had no symptoms except chronic retention of urine, and it seemed that by relief of this and the establishment of better drainage, improvement might result, and the pyelonephritic kidneys be given a chance to function better. His readings led him to agree with others that leukoplakia of the urinary tract usually occurred in cases of chronic infection of that tract, and of those who have had an obstruction to the normal outlet of urine; that syphilis might be an etiological factor; that syphilis might have existed in an individual prior to his having acquired syphilis or gonorrhea, and as a result of these infections, the lesion might be brought into activity.

Complete Ablation of External Genitalia.—Dr. Terry M. Townsend, who described this case, said that it was impossible to present the patient, since he was an inmate of Sing Sing Prison, but he wished to submit the specimen and the report because of unusually interesting features connected with them. The patient, twenty-four years of age and colored, had had for a long time a condition of the prepuce that would not heal. He had had radium treatment, and repeated doses of salvarsan, all without effect, and his condition grew steadily worse, until, when admitted to the prison, an extensive ulceration of the prepuce was found. A complete extirpation seemed the only chance of saving his life. The operation was performed, and the specimen, removed *en masse*, contained the upper segmental triangle, the lymph nodes of the pubic region, the fat, the mons veneris, penis, scrotum, and testes. Then incision was made into Scarpa's triangle, where were found two or three lymph nodes which drained into the superficial inguinal nodes, so it was necessary to clear the region of the saphenous vein. This was done, carrying the incision downward, and a plastic operation was performed. This was the most troublesome part of the work, as at first it did not hold, but good results were finally secured, and the man was soon able to be up and about. The plastic part of the tension would still have to be watched.

Some Unique Blood Chemistry Findings.—Dr. Joseph F. McCarthy and Dr. Killian presented this paper, which related to a patient who had had a pyelogram done on him, the medium employed having been bismuth and ammonium citrate, twenty-five per cent. solution, four days following which there supervened almost complete anuria, which lasted for several days. The blood chemistry findings during the critical period revealed 23.1 mgm. of creatinin to 100 c.c., and 104 mgm. urea nitrogen. The usual measures having been exhausted and proved fruitless, the employment of the duodenal tube was considered and inaugurated with the most striking benefit, there having been a pronounced amelioration of vomiting, an enormously increased output of urine, but little effect upon the urea nitrogen and creatinin until grand lavage with tap water and soda bicarbonate was instituted by means of this tube. Within five or six days following the beginning of the lavage, the blood picture demonstrated a spectacular improvement. This continued until normal findings were encountered. During this period a small calculus was passed, which undoubtedly was the causative factor. The writers advocated the use of the duodenal tube in cases such as those of drug poisoning, postoperative prostate, etc., wherein there occurred a rapid accumulation of nitrogenous contents in the blood, but where the renal parenchyma was not destroyed by chronic pathological change.

Metastatic Abscesses of Both Kidneys.—Dr. Edwin Beer presented a patient illustrating a group rarely observed. On May 16th an operation had been performed under the diagnosis of left perinephritic abscess, probably due to cortical abscess of the left kidney. Eight days afterward, the temperature suddenly rose to 105°; this was relieved, but went up again on the 26th, with pain in the opposite kidney. Three days a similar operation was done on the right kidney. After this, the patient made an uninterrupted recovery.
